Table of Contents

Table of Contents.....	i
Introduction.....	xi
1 General	1
1.1 Scope	2
1.1.1 Extent.....	3
1.1.2 Structure.....	3
1.1.3 Conformity of an Implementation with the Standard	9
1.1.4 Method of Description and Syntax Notation.....	12
1.1.5 Classification of Errors	15
1.2 Normative References	16
1.3 Terms and Definitions	17
2 Lexical Elements.....	19
2.1 Character Set	19
2.2 Lexical Elements, Separators, and Delimiters	23
2.3 Identifiers.....	24
2.4 Numeric Literals.....	26
2.4.1 Decimal Literals	26
2.4.2 Based Literals	27
2.5 Character Literals	28
2.6 String Literals.....	28
2.7 Comments	29
2.8 Pragmas.....	29
2.9 Reserved Words	34
3 Declarations and Types.....	37
3.1 Declarations	37
3.2 Types and Subtypes	40
3.2.1 Type Declarations.....	44
3.2.2 Subtype Declarations	46
3.2.3 Classification of Operations	47
3.2.4 Subtype Predicates	49
3.3 Objects and Named Numbers.....	51
3.3.1 Object Declarations	54
3.3.2 Number Declarations	59
3.4 Derived Types and Classes	60
3.4.1 Derivation Classes	67
3.5 Scalar Types.....	69
3.5.1 Enumeration Types	76
3.5.2 Character Types	78
3.5.3 Boolean Types	80
3.5.4 Integer Types	80
3.5.5 Operations of Discrete Types.....	85
3.5.6 Real Types.....	86
3.5.7 Floating Point Types	88
3.5.8 Operations of Floating Point Types	90

3.5.9 Fixed Point Types.....	91
3.5.10 Operations of Fixed Point Types	93
3.6 Array Types	95
3.6.1 Index Constraints and Discrete Ranges	98
3.6.2 Operations of Array Types	100
3.6.3 String Types.....	101
3.7 Discriminants.....	102
3.7.1 Discriminant Constraints.....	108
3.7.2 Operations of Discriminated Types	110
3.8 Record Types	111
3.8.1 Variant Parts and Discrete Choices.....	115
3.9 Tagged Types and Type Extensions.....	118
3.9.1 Type Extensions.....	126
3.9.2 Dispatching Operations of Tagged Types	128
3.9.3 Abstract Types and Subprograms.....	134
3.9.4 Interface Types	139
3.10 Access Types.....	143
3.10.1 Incomplete Type Declarations	148
3.10.2 Operations of Access Types	153
3.11 Declarative Parts	166
3.11.1 Completions of Declarations.....	168
4 Names and Expressions	171
4.1 Names.....	171
4.1.1 Indexed Components.....	173
4.1.2 Slices	174
4.1.3 Selected Components.....	175
4.1.4 Attributes	178
4.1.5 User-Defined References.....	180
4.1.6 User-Defined Indexing	182
4.2 Literals.....	183
4.3 Aggregates.....	185
4.3.1 Record Aggregates	186
4.3.2 Extension Aggregates	190
4.3.3 Array Aggregates	192
4.4 Expressions	197
4.5 Operators and Expression Evaluation	199
4.5.1 Logical Operators and Short-circuit Control Forms	200
4.5.2 Relational Operators and Membership Tests	202
4.5.3 Binary Adding Operators.....	208
4.5.4 Unary Adding Operators.....	210
4.5.5 Multiplying Operators	210
4.5.6 Highest Precedence Operators	213
4.5.7 Conditional Expressions	214
4.5.8 Quantified Expressions	217
4.6 Type Conversions	218
4.7 Qualified Expressions.....	227
4.8 Allocators	228
4.9 Static Expressions and Static Subtypes	233
4.9.1 Statically Matching Constraints and Subtypes	239

5	Statements	241
5.1	Simple and Compound Statements - Sequences of Statements	241
5.2	Assignment Statements	243
5.3	If Statements	246
5.4	Case Statements	247
5.5	Loop Statements	250
5.5.1	User-Defined Iterator Types	252
5.5.2	Generalized Loop Iteration	253
5.6	Block Statements	255
5.7	Exit Statements	256
5.8	Goto Statements	257
6	Subprograms	259
6.1	Subprogram Declarations	259
6.1.1	Preconditions and Postconditions	263
6.2	Formal Parameter Modes	268
6.3	Subprogram Bodies	270
6.3.1	Conformance Rules	272
6.3.2	Inline Expansion of Subprograms	276
6.4	Subprogram Calls	277
6.4.1	Parameter Associations	279
6.5	Return Statements	285
6.5.1	Nonreturning Procedures	292
6.6	Overloading of Operators	293
6.7	Null Procedures	294
6.8	Expression Functions	295
7	Packages	297
7.1	Package Specifications and Declarations	297
7.2	Package Bodies	298
7.3	Private Types and Private Extensions	300
7.3.1	Private Operations	307
7.3.2	Type Invariants	311
7.4	Deferred Constants	314
7.5	Limited Types	316
7.6	Assignment and Finalization	320
7.6.1	Completion and Finalization	326
8	Visibility Rules	335
8.1	Declarative Region	335
8.2	Scope of Declarations	337
8.3	Visibility	340
8.3.1	Overriding Indicators	347
8.4	Use Clauses	348
8.5	Renaming Declarations	351
8.5.1	Object Renaming Declarations	352
8.5.2	Exception Renaming Declarations	355
8.5.3	Package Renaming Declarations	355
8.5.4	Subprogram Renaming Declarations	356
8.5.5	Generic Renaming Declarations	359
8.6	The Context of Overload Resolution	360

9	Tasks and Synchronization	367
9.1	Task Units and Task Objects	368
9.2	Task Execution - Task Activation	372
9.3	Task Dependence - Termination of Tasks	373
9.4	Protected Units and Protected Objects	375
9.5	Intertask Communication	381
9.5.1	Protected Subprograms and Protected Actions	384
9.5.2	Entries and Accept Statements	386
9.5.3	Entry Calls	390
9.5.4	Requeue Statements	394
9.6	Delay Statements, Duration, and Time	396
9.6.1	Formatting, Time Zones, and other operations for Time	400
9.7	Select Statements	408
9.7.1	Selective Accept	408
9.7.2	Timed Entry Calls	410
9.7.3	Conditional Entry Calls	412
9.7.4	Asynchronous Transfer of Control	412
9.8	Abort of a Task - Abort of a Sequence of Statements	414
9.9	Task and Entry Attributes	416
9.10	Shared Variables	417
9.11	Example of Tasking and Synchronization	419
10	Program Structure and Compilation Issues	421
10.1	Separate Compilation	421
10.1.1	Compilation Units - Library Units	422
10.1.2	Context Clauses - With Clauses	429
10.1.3	Subunits of Compilation Units	434
10.1.4	The Compilation Process	436
10.1.5	Pragmas and Program Units	439
10.1.6	Environment-Level Visibility Rules	440
10.2	Program Execution	442
10.2.1	Elaboration Control	446
11	Exceptions	455
11.1	Exception Declarations	455
11.2	Exception Handlers	456
11.3	Raise Statements	458
11.4	Exception Handling	459
11.4.1	The Package Exceptions	460
11.4.2	Pragmas Assert and Assertion_Policy	465
11.4.3	Example of Exception Handling	468
11.5	Suppressing Checks	469
11.6	Exceptions and Optimization	473
12	Generic Units	477
12.1	Generic Declarations	477
12.2	Generic Bodies	479
12.3	Generic Instantiation	480
12.4	Formal Objects	489
12.5	Formal Types	491
12.5.1	Formal Private and Derived Types	494

12.5.2 Formal Scalar Types	499
12.5.3 Formal Array Types	500
12.5.4 Formal Access Types	501
12.5.5 Formal Interface Types	502
12.6 Formal Subprograms	503
12.7 Formal Packages	507
12.8 Example of a Generic Package.....	510
13 Representation Issues.....	513
13.1 Operational and Representation Aspects	513
13.1.1 Aspect Specifications	523
13.2 Packed Types	527
13.3 Operational and Representation Attributes	529
13.4 Enumeration Representation Clauses	543
13.5 Record Layout.....	545
13.5.1 Record Representation Clauses	545
13.5.2 Storage Place Attributes	549
13.5.3 Bit Ordering.....	550
13.6 Change of Representation	551
13.7 The Package System	552
13.7.1 The Package System.Storage_Elements	555
13.7.2 The Package System.Address_To_Access_Conversions.....	557
13.8 Machine Code Insertions	558
13.9 Unchecked Type Conversions.....	559
13.9.1 Data Validity	561
13.9.2 The Valid Attribute.....	564
13.10 Unchecked Access Value Creation.....	565
13.11 Storage Management	566
13.11.1 Storage Allocation Attributes	572
13.11.2 Unchecked Storage Deallocation.....	573
13.11.3 Default Storage Pools	575
13.11.4 Storage Subpools.....	577
13.11.5 Subpool Reclamation.....	580
13.11.6 Storage Subpool Example	581
13.12 Pragma Restrictions and Pragma Profile	583
13.12.1 Language-Defined Restrictions and Profiles	585
13.13 Streams.....	588
13.13.1 The Package Streams	588
13.13.2 Stream-Oriented Attributes	590
13.14 Freezing Rules	599
The Standard Libraries	609
Annex A (normative) Predefined Language Environment	611
A.1 The Package Standard.....	615
A.2 The Package Ada	621
A.3 Character Handling	621
A.3.1 The Packages Characters, Wide_Characters, and Wide_Wide_Characters.....	622
A.3.2 The Package Characters.Handling.....	622
A.3.3 The Package Characters.Latin_1.....	626
A.3.4 The Package Characters.Conversions	630

A.3.5 The Package Wide_Characters.Handling	632
A.3.6 The Package Wide_Wide_Characters.Handling	635
A.4 String Handling	635
A.4.1 The Package Strings	636
A.4.2 The Package Strings.Maps	636
A.4.3 Fixed-Length String Handling	640
A.4.4 Bounded-Length String Handling	649
A.4.5 Unbounded-Length String Handling	657
A.4.6 String-Handling Sets and Mappings	663
A.4.7 Wide_String Handling	663
A.4.8 Wide_Wide_String Handling	666
A.4.9 String Hashing	669
A.4.10 String Comparison	671
A.4.11 String Encoding	672
A.5 The Numerics Packages	678
A.5.1 Elementary Functions	678
A.5.2 Random Number Generation	682
A.5.3 Attributes of Floating Point Types	688
A.5.4 Attributes of Fixed Point Types	695
A.6 Input-Output	695
A.7 External Files and File Objects	696
A.8 Sequential and Direct Files	697
A.8.1 The Generic Package Sequential_IO	698
A.8.2 File Management	699
A.8.3 Sequential Input-Output Operations	701
A.8.4 The Generic Package Direct_IO	702
A.8.5 Direct Input-Output Operations	703
A.9 The Generic Package Storage_IO	704
A.10 Text Input-Output	705
A.10.1 The Package Text_IO	706
A.10.2 Text File Management	712
A.10.3 Default Input, Output, and Error Files	713
A.10.4 Specification of Line and Page Lengths	714
A.10.5 Operations on Columns, Lines, and Pages	715
A.10.6 Get and Put Procedures	718
A.10.7 Input-Output of Characters and Strings	719
A.10.8 Input-Output for Integer Types	722
A.10.9 Input-Output for Real Types	723
A.10.10 Input-Output for Enumeration Types	726
A.10.11 Input-Output for Bounded Strings	728
A.10.12 Input-Output for Unbounded Strings	729
A.11 Wide Text Input-Output and Wide Wide Text Input-Output	730
A.12 Stream Input-Output	731
A.12.1 The Package Streams.Stream_IO	731
A.12.2 The Package Text_IO.Text_Streams	735
A.12.3 The Package Wide_Text_IO.Text_Streams	735
A.12.4 The Package Wide_Wide_Text_IO.Text_Streams	735
A.13 Exceptions in Input-Output	736
A.14 File Sharing	737
A.15 The Package Command_Line	738

A.16 The Package Directories	739
A.16.1 The Package Directories.Hierarchical_File_Names.....	750
A.17 The Package Environment_Variables	753
A.18 Containers	755
A.18.1 The Package Containers	757
A.18.2 The Generic Package Containers.Vectors.....	758
A.18.3 The Generic Package Containers.Doubly_Linked_Lists.....	779
A.18.4 Maps.....	793
A.18.5 The Generic Package Containers.Hashed_Maps.....	802
A.18.6 The Generic Package Containers.Ordered_Maps.....	807
A.18.7 Sets	813
A.18.8 The Generic Package Containers.Hashed_Sets	823
A.18.9 The Generic Package Containers.Ordered_Sets	828
A.18.10 The Generic Package Containers.Multiway_Trees	835
A.18.11 The Generic Package Containers.Indefinite_Vectors.....	853
A.18.12 The Generic Package Containers.Indefinite_Doubly_Linked_Lists.....	853
A.18.13 The Generic Package Containers.Indefinite_Hashed_Maps.....	854
A.18.14 The Generic Package Containers.Indefinite_Ordered_Maps.....	854
A.18.15 The Generic Package Containers.Indefinite_Hashed_Sets	855
A.18.16 The Generic Package Containers.Indefinite_Ordered_Sets	855
A.18.17 The Generic Package Containers.Indefinite_Multiway_Trees	856
A.18.18 The Generic Package Containers.Indefinite_Holders.....	856
A.18.19 The Generic Package Containers.Bounded_Vectors	861
A.18.20 The Generic Package Containers.Bounded_Doubly_Linked_Lists	862
A.18.21 The Generic Package Containers.Bounded_Hashed_Maps	864
A.18.22 The Generic Package Containers.Bounded_Ordered_Maps	866
A.18.23 The Generic Package Containers.Bounded_Hashed_Sets.....	867
A.18.24 The Generic Package Containers.Bounded_Ordered_Sets.....	869
A.18.25 The Generic Package Containers.Bounded_Multiway_Trees.....	870
A.18.26 Array Sorting	872
A.18.27 The Generic Package Containers.Synchronized_Queue_Interfaces	874
A.18.28 The Generic Package Containers.Unbounded_Synchronized_Queues	875
A.18.29 The Generic Package Containers.Bounded_Synchronized_Queues.....	876
A.18.30 The Generic Package Containers.Unbounded_Priority_Queues	877
A.18.31 The Generic Package Containers.Bounded_Priority_Queues.....	878
A.18.32 Example of Container Use	880
A.19 The Package Locales	882
Annex B (normative) Interface to Other Languages.....	885
B.1 Interfacing Aspects	885
B.2 The Package Interfaces	890
B.3 Interfacing with C and C++	892
B.3.1 The Package Interfaces.C.Strings	900
B.3.2 The Generic Package Interfaces.C.Pointers.....	903
B.3.3 Unchecked Union Types	906
B.4 Interfacing with COBOL.....	909
B.5 Interfacing with Fortran	916
Annex C (normative) Systems Programming	919
C.1 Access to Machine Operations	919
C.2 Required Representation Support.....	920

C.3 Interrupt Support	920
C.3.1 Protected Procedure Handlers	923
C.3.2 The Package Interrupts	926
C.4 Preelaboration Requirements	928
C.5 Pragma Discard_Names	930
C.6 Shared Variable Control	931
C.7 Task Information	935
C.7.1 The Package Task_Identification	935
C.7.2 The Package Task_Attributes	937
C.7.3 The Package Task_Termination	940
Annex D (normative) Real-Time Systems	943
D.1 Task Priorities	943
D.2 Priority Scheduling	946
D.2.1 The Task Dispatching Model	946
D.2.2 Task Dispatching Pragmas	948
D.2.3 Preemptive Dispatching	950
D.2.4 Non-Preemptive Dispatching	951
D.2.5 Round Robin Dispatching	953
D.2.6 Earliest Deadline First Dispatching	955
D.3 Priority Ceiling Locking	958
D.4 Entry Queuing Policies	961
D.5 Dynamic Priorities	963
D.5.1 Dynamic Priorities for Tasks	963
D.5.2 Dynamic Priorities for Protected Objects	965
D.6 Preemptive Abort	966
D.7 Tasking Restrictions	967
D.8 Monotonic Time	971
D.9 Delay Accuracy	975
D.10 Synchronous Task Control	977
D.10.1 Synchronous Barriers	978
D.11 Asynchronous Task Control	979
D.12 Other Optimizations and Determinism Rules	980
D.13 The Ravenscar Profile	981
D.14 Execution Time	983
D.14.1 Execution Time Timers	986
D.14.2 Group Execution Time Budgets	988
D.14.3 Execution Time of Interrupt Handlers	991
D.15 Timing Events	991
D.16 Multiprocessor Implementation	994
D.16.1 Multiprocessor Dispatching Domains	995
Annex E (normative) Distributed Systems	999
E.1 Partitions	999
E.2 Categorization of Library Units	1001
E.2.1 Shared Passive Library Units	1002
E.2.2 Remote Types Library Units	1003
E.2.3 Remote Call Interface Library Units	1006
E.3 Consistency of a Distributed System	1008
E.4 Remote Subprogram Calls	1009
E.4.1 Asynchronous Remote Calls	1013

E.4.2 Example of Use of a Remote Access-to-Class-Wide Type.....	1014
E.5 Partition Communication Subsystem.....	1016
Annex F (normative) Information Systems	1021
F.1 Machine_Radix Attribute Definition Clause	1021
F.2 The Package Decimal.....	1022
F.3 Edited Output for Decimal Types	1023
F.3.1 Picture String Formation	1024
F.3.2 Edited Output Generation.....	1028
F.3.3 The Package Text_IO.Editing	1032
F.3.4 The Package Wide_Text_IO.Editing	1035
F.3.5 The Package Wide_Wide_Text_IO.Editing.....	1036
Annex G (normative) Numerics.....	1037
G.1 Complex Arithmetic	1037
G.1.1 Complex Types	1038
G.1.2 Complex Elementary Functions	1043
G.1.3 Complex Input-Output.....	1047
G.1.4 The Package Wide_Text_IO.Complex_IO	1051
G.1.5 The Package Wide_Wide_Text_IO.Complex_IO	1051
G.2 Numeric Performance Requirements.....	1051
G.2.1 Model of Floating Point Arithmetic	1052
G.2.2 Model-Oriented Attributes of Floating Point Types	1054
G.2.3 Model of Fixed Point Arithmetic.....	1056
G.2.4 Accuracy Requirements for the Elementary Functions	1058
G.2.5 Performance Requirements for Random Number Generation	1060
G.2.6 Accuracy Requirements for Complex Arithmetic	1062
G.3 Vector and Matrix Manipulation.....	1064
G.3.1 Real Vectors and Matrices	1065
G.3.2 Complex Vectors and Matrices	1071
Annex H (normative) High Integrity Systems.....	1083
H.1 Pragma Normalize_Scalars	1083
H.2 Documentation of Implementation Decisions	1084
H.3 Reviewable Object Code	1085
H.3.1 Pragma Reviewable	1085
H.3.2 Pragma Inspection_Point.....	1087
H.4 High Integrity Restrictions	1088
H.5 Pragma Detect_Blocking.....	1092
H.6 Pragma Partition_Elaboration_Policy	1093
Annex J (normative) Obsolescent Features	1095
J.1 Renamings of Library Units	1095
J.2 Allowed Replacements of Characters	1096
J.3 Reduced Accuracy Subtypes	1096
J.4 The Constrained Attribute.....	1097
J.5 ASCII	1098

Introduction

- This is the Annotated Ada Reference Manual. 1
- Other available Ada documents include: 2
- *{AI95-00387-01}* *{AI05-0245-1}* Ada 2012 Rationale. This gives an introduction to the changes and new features in Ada 2012, and explains the rationale behind them. Programmers should read this rationale before reading this Standard in depth. Rationales for Ada 83, Ada 95, and Ada 2005 are also available. 3/3
 - **Discussion:** *{AI05-0245-1}* As of this writing (December 2012), only five chapters of the Ada 2012 Rationale have been published. Additional chapters are in development and should be published during 2013. 3.a/3
 - *This paragraph was deleted.* 4/1
 - The Ada Reference Manual (RM). This is the International Standard — ISO/IEC 8652:201x. 5/3

Design Goals

{AI95-00387-01} Ada was originally designed with three overriding concerns: program reliability and maintenance, programming as a human activity, and efficiency. The 1995 revision to the language was designed to provide greater flexibility and extensibility, additional control over storage management and synchronization, and standardized packages oriented toward supporting important application areas, while at the same time retaining the original emphasis on reliability, maintainability, and efficiency. This third edition provides further flexibility and adds more standardized packages within the framework provided by the 1995 revision. 6/3

The need for languages that promote reliability and simplify maintenance is well established. Hence emphasis was placed on program readability over ease of writing. For example, the rules of the language require that program variables be explicitly declared and that their type be specified. Since the type of a variable is invariant, compilers can ensure that operations on variables are compatible with the properties intended for objects of the type. Furthermore, error-prone notations have been avoided, and the syntax of the language avoids the use of encoded forms in favor of more English-like constructs. Finally, the language offers support for separate compilation of program units in a way that facilitates program development and maintenance, and which provides the same degree of checking between units as within a unit. 7

Concern for the human programmer was also stressed during the design. Above all, an attempt was made to keep to a relatively small number of underlying concepts integrated in a consistent and systematic way while continuing to avoid the pitfalls of excessive involution. The design especially aims to provide language constructs that correspond intuitively to the normal expectations of users. 8

Like many other human activities, the development of programs is becoming ever more decentralized and distributed. Consequently, the ability to assemble a program from independently produced software components continues to be a central idea in the design. The concepts of packages, of private types, and of generic units are directly related to this idea, which has ramifications in many other aspects of the language. An allied concern is the maintenance of programs to match changing requirements; type extension and the hierarchical library enable a program to be modified while minimizing disturbance to existing tested and trusted components. 9

No language can avoid the problem of efficiency. Languages that require over-elaborate compilers, or that lead to the inefficient use of storage or execution time, force these inefficiencies on all machines and on all programs. Every construct of the language was examined in the light of present implementation techniques. Any proposed construct whose implementation was unclear or that required excessive machine resources was rejected. 10

Language Summary

- 11 An Ada program is composed of one or more program units. Program units may be subprograms (which define executable algorithms), packages (which define collections of entities), task units (which define concurrent computations), protected units (which define operations for the coordinated sharing of data between tasks), or generic units (which define parameterized forms of packages and subprograms). Each program unit normally consists of two parts: a specification, containing the information that must be visible to other units, and a body, containing the implementation details, which need not be visible to other units. Most program units can be compiled separately.
- 12 This distinction of the specification and body, and the ability to compile units separately, allows a program to be designed, written, and tested as a set of largely independent software components.
- 13 An Ada program will normally make use of a library of program units of general utility. The language provides means whereby individual organizations can construct their own libraries. All libraries are structured in a hierarchical manner; this enables the logical decomposition of a subsystem into individual components. The text of a separately compiled program unit must name the library units it requires.
- 14 *Program Units*
- 15 A subprogram is the basic unit for expressing an algorithm. There are two kinds of subprograms: procedures and functions. A procedure is the means of invoking a series of actions. For example, it may read data, update variables, or produce some output. It may have parameters, to provide a controlled means of passing information between the procedure and the point of call. A function is the means of invoking the computation of a value. It is similar to a procedure, but in addition will return a result.
- 16 A package is the basic unit for defining a collection of logically related entities. For example, a package can be used to define a set of type declarations and associated operations. Portions of a package can be hidden from the user, thus allowing access only to the logical properties expressed by the package specification.
- 17 Subprogram and package units may be compiled separately and arranged in hierarchies of parent and child units giving fine control over visibility of the logical properties and their detailed implementation.
- 18 A task unit is the basic unit for defining a task whose sequence of actions may be executed concurrently with those of other tasks. Such tasks may be implemented on multicomputers, multiprocessors, or with interleaved execution on a single processor. A task unit may define either a single executing task or a task type permitting the creation of any number of similar tasks.
- 19/2 {AI95-00114-01} A protected unit is the basic unit for defining protected operations for the coordinated use of data shared between tasks. Simple mutual exclusion is provided automatically, and more elaborate sharing protocols can be defined. A protected operation can either be a subprogram or an entry. A protected entry specifies a Boolean expression (an entry barrier) that must be True before the body of the entry is executed. A protected unit may define a single protected object or a protected type permitting the creation of several similar objects.
- 20 *Declarations and Statements*
- 21 The body of a program unit generally contains two parts: a declarative part, which defines the logical entities to be used in the program unit, and a sequence of statements, which defines the execution of the program unit.
- 22 The declarative part associates names with declared entities. For example, a name may denote a type, a constant, a variable, or an exception. A declarative part also introduces the names and parameters of other nested subprograms, packages, task units, protected units, and generic units to be used in the program unit.

- The sequence of statements describes a sequence of actions that are to be performed. The statements are executed in succession (unless a transfer of control causes execution to continue from another place). 23
- An assignment statement changes the value of a variable. A procedure call invokes execution of a procedure after associating any actual parameters provided at the call with the corresponding formal parameters. 24
- Case statements and if statements allow the selection of an enclosed sequence of statements based on the value of an expression or on the value of a condition. 25
- The loop statement provides the basic iterative mechanism in the language. A loop statement specifies that a sequence of statements is to be executed repeatedly as directed by an iteration scheme, or until an exit statement is encountered. 26
- A block statement comprises a sequence of statements preceded by the declaration of local entities used by the statements. 27
- Certain statements are associated with concurrent execution. A delay statement delays the execution of a task for a specified duration or until a specified time. An entry call statement is written as a procedure call statement; it requests an operation on a task or on a protected object, blocking the caller until the operation can be performed. A called task may accept an entry call by executing a corresponding accept statement, which specifies the actions then to be performed as part of the rendezvous with the calling task. An entry call on a protected object is processed when the corresponding entry barrier evaluates to true, whereupon the body of the entry is executed. The requeue statement permits the provision of a service as a number of related activities with preference control. One form of the select statement allows a selective wait for one of several alternative rendezvous. Other forms of the select statement allow conditional or timed entry calls and the asynchronous transfer of control in response to some triggering event. 28
- Execution of a program unit may encounter error situations in which normal program execution cannot continue. For example, an arithmetic computation may exceed the maximum allowed value of a number, or an attempt may be made to access an array component by using an incorrect index value. To deal with such error situations, the statements of a program unit can be textually followed by exception handlers that specify the actions to be taken when the error situation arises. Exceptions can be raised explicitly by a raise statement. 29
- Data Types* 30
- Every object in the language has a type, which characterizes a set of values and a set of applicable operations. The main classes of types are elementary types (comprising enumeration, numeric, and access types) and composite types (including array and record types). 31
- {AI95-00285-01} {AI95-00387-01} An enumeration type defines an ordered set of distinct enumeration literals, for example a list of states or an alphabet of characters. The enumeration types Boolean, Character, Wide_Character, and Wide_Wide_Character are predefined. 32/2
- Numeric types provide a means of performing exact or approximate numerical computations. Exact computations use integer types, which denote sets of consecutive integers. Approximate computations use either fixed point types, with absolute bounds on the error, or floating point types, with relative bounds on the error. The numeric types Integer, Float, and Duration are predefined. 33
- {AI95-00285-01} {AI95-00387-01} Composite types allow definitions of structured objects with related components. The composite types in the language include arrays and records. An array is an object with indexed components of the same type. A record is an object with named components of possibly different types. Task and protected types are also forms of composite types. The array types String, Wide_String, and Wide_Wide_String are predefined. 34/2

- 35 Record, task, and protected types may have special components called discriminants which parameterize the type. Variant record structures that depend on the values of discriminants can be defined within a record type.
- 36 Access types allow the construction of linked data structures. A value of an access type represents a reference to an object declared as aliased or to an object created by the evaluation of an allocator. Several variables of an access type may designate the same object, and components of one object may designate the same or other objects. Both the elements in such linked data structures and their relation to other elements can be altered during program execution. Access types also permit references to subprograms to be stored, passed as parameters, and ultimately dereferenced as part of an indirect call.
- 37 Private types permit restricted views of a type. A private type can be defined in a package so that only the logically necessary properties are made visible to the users of the type. The full structural details that are externally irrelevant are then only available within the package and any child units.
- 38 From any type a new type may be defined by derivation. A type, together with its derivatives (both direct and indirect) form a derivation class. Class-wide operations may be defined that accept as a parameter an operand of any type in a derivation class. For record and private types, the derivatives may be extensions of the parent type. Types that support these object-oriented capabilities of class-wide operations and type extension must be tagged, so that the specific type of an operand within a derivation class can be identified at run time. When an operation of a tagged type is applied to an operand whose specific type is not known until run time, implicit dispatching is performed based on the tag of the operand.
- 38.1/2 {AI95-00387-01} Interface types provide abstract models from which other interfaces and types may be composed and derived. This provides a reliable form of multiple inheritance. Interface types may also be implemented by task types and protected types thereby enabling concurrent programming and inheritance to be merged.
- 39 The concept of a type is further refined by the concept of a subtype, whereby a user can constrain the set of allowed values of a type. Subtypes can be used to define subranges of scalar types, arrays with a limited set of index values, and records and private types with particular discriminant values.
- 40 *Other Facilities*
- 41/2 {AI95-00387-01} Aspect clauses can be used to specify the mapping between types and features of an underlying machine. For example, the user can specify that objects of a given type must be represented with a given number of bits, or that the components of a record are to be represented using a given storage layout. Other features allow the controlled use of low level, nonportable, or implementation-dependent aspects, including the direct insertion of machine code.
- 42/2 {AI95-00387-01} The predefined environment of the language provides for input-output and other capabilities by means of standard library packages. Input-output is supported for values of user-defined as well as of predefined types. Standard means of representing values in display form are also provided.
- 42.1/2 {AI95-00387-01} The predefined standard library packages provide facilities such as string manipulation, containers of various kinds (vectors, lists, maps, etc.), mathematical functions, random number generation, and access to the execution environment.
- 42.2/2 {AI95-00387-01} The specialized annexes define further predefined library packages and facilities with emphasis on areas such as real-time scheduling, interrupt handling, distributed systems, numerical computation, and high-integrity systems.
- 43 Finally, the language provides a powerful means of parameterization of program units, called generic program units. The generic parameters can be types and subprograms (as well as objects and packages)

and so allow general algorithms and data structures to be defined that are applicable to all types of a given class.

Language Changes

Paragraphs 44 through 57 have been removed as they described differences from the first edition of Ada (Ada 83).

{AI95-00387-01} This International Standard replaces the second edition of 1995. It modifies the previous edition by making changes and additions that improve the capability of the language and the reliability of programs written in the language. This edition incorporates the changes from Amendment 1 (ISO/IEC 8652:1995:AMD 1:2007), which were designed to improve the portability of programs, interfacing to other languages, and both the object-oriented and real-time capabilities. 57.1/3

{AI95-00387-01} {AI05-0299-1} Significant changes originating in Amendment 1 are incorporated: 57.2/3

- Support for program text is extended to cover the entire ISO/IEC 10646:2003 repertoire. Execution support now includes the 32-bit character set. See subclauses 2.1, 3.5.2, 3.6.3, A.1, A.3, and A.4. 57.3/3
- The object-oriented model has been improved by the addition of an interface facility which provides multiple inheritance and additional flexibility for type extensions. See subclauses 3.4, 3.9, and 7.3. An alternative notation for calling operations more akin to that used in other languages has also been added. See subclause 4.1.3. 57.4/3
- Access types have been further extended to unify properties such as the ability to access constants and to exclude null values. See clause 3.10. Anonymous access types are now permitted more freely and anonymous access-to-subprogram types are introduced. See subclauses 3.3, 3.6, 3.10, and 8.5.1. 57.5/3
- The control of structure and visibility has been enhanced to permit mutually dependent references between units and finer control over access from the private part of a package. See subclauses 3.10.1 and 10.1.2. In addition, limited types have been made more useful by the provision of aggregates, constants, and constructor functions. See subclauses 4.3, 6.5, and 7.5. 57.6/3
- The predefined environment has been extended to include additional time and calendar operations, improved string handling, a comprehensive container library, file and directory management, and access to environment variables. See subclauses 9.6.1, A.4, A.16, A.17, and A.18. 57.7/3
- Two of the Specialized Needs Annexes have been considerably enhanced: 57.8/3
 - The Real-Time Systems Annex now includes the Ravenscar profile for high-integrity systems, further dispatching policies such as Round Robin and Earliest Deadline First, support for timing events, and support for control of CPU time utilization. See subclauses D.2, D.13, D.14, and D.15. 57.9/2
 - The Numerics Annex now includes support for real and complex vectors and matrices as previously defined in ISO/IEC 13813:1997 plus further basic operations for linear algebra. See subclause G.3. 57.10/3
- The overall reliability of the language has been enhanced by a number of improvements. These include new syntax which detects accidental overloading, as well as pragmas for making assertions and giving better control over the suppression of checks. See subclauses 6.1, 11.4.2, and 11.5. 57.11/3

{AI05-0245-1} In addition, this third edition makes enhancements to address two important issues, namely, the particular problems of multiprocessor architectures, and the need to further increase the capabilities regarding assertions for correctness. It also makes additional changes and additions that improve the capability of the language and the reliability of programs written in the language. 57.12/3

- 57.13/3 {AI05-0245-1} {AI05-0299-1} The following significant changes with respect to the 1995 edition as amended by Amendment 1 are incorporated:
- 57.14/3 • New syntax (the aspect specification) is introduced to enable properties to be specified for various entities in a more structured manner than through pragmas. See subclause 13.1.1.
 - 57.15/3 • The concept of assertions introduced in the 2005 edition is extended with the ability to specify preconditions and postconditions for subprograms, and invariants for private types. The concept of constraints in defining subtypes is supplemented with subtype predicates that enable subsets to be specified other than as simple ranges. These properties are all indicated using aspect specifications. See subclauses 3.2.4, 6.1.1, and 7.3.2.
 - 57.16/3 • New forms of expressions are introduced. These are if expressions, case expressions, quantified expressions, and expression functions. As well as being useful for programming in general by avoiding the introduction of unnecessary assignments, they are especially valuable in conditions and invariants since they avoid the need to introduce auxiliary functions. See subclauses 4.5.7, 4.5.8, and 6.8. Membership tests are also made more flexible. See subclauses 4.4 and 4.5.2.
 - 57.17/3 • A number of changes are made to subprogram parameters. Functions may now have parameters of all modes. In order to mitigate consequent (and indeed existing) problems of inadvertent order dependence, rules are introduced to reduce aliasing. A parameter may now be explicitly marked as aliased and the type of a parameter may be incomplete in certain circumstances. See subclauses 3.10.1, 6.1, and 6.4.1.
 - 57.18/3 • The use of access types is now more flexible. The rules for accessibility and certain conversions are improved. See subclauses 3.10.2, 4.5.2, 4.6, and 8.6. Furthermore, better control of storage pools is provided. See subclause 13.11.4.
 - 57.19/3 • The Real-Time Systems Annex now includes facilities for defining domains of processors and assigning tasks to them. Improvements are made to scheduling and budgeting facilities. See subclauses D.10.1, D.14, and D.16.
 - 57.20/3 • A number of important improvements are made to the standard library. These include packages for conversions between strings and UTF encodings, and classification functions for wide and wide wide characters. Internationalization is catered for by a package giving locale information. See subclauses A.3, A.4.11, and A.19. The container library is extended to include bounded forms of the existing containers and new containers for indefinite objects, multiway trees, and queues. See subclause A.18.
 - 57.21/3 • Finally, certain features are added primarily to ease the use of containers, such as the ability to iterate over all elements in a container without having to encode the iteration. These can also be used for iteration over arrays, and within quantified expressions. See subclauses 4.1.5, 4.1.6, 5.5.1, and 5.5.2.

Instructions for Comment Submission

Informal comments on this International Standard may be sent via e-mail to **ada-comment@ada-auth.org**. If appropriate, the Project Editor will initiate the defect correction procedure. 58/1

Comments should use the following format: 59

```

!topic Title summarizing comment
!reference Ada 2012 RMss.ss(pp)
!from Author Name yy-mm-dd
!keywords keywords related to topic
!discussion

```

text of discussion

where *ss.ss* is the clause or subclause number, *pp* is the paragraph number where applicable, and *yy-mm-dd* is the date the comment was sent. The date is optional, as is the **!keywords** line. 61/3

Please use a descriptive “Subject” in your e-mail message, and limit each message to a single comment. 62/1

When correcting typographical errors or making minor wording suggestions, please put the correction directly as the topic of the comment; use square brackets [] to indicate text to be omitted and curly braces { } to indicate text to be added, and provide enough context to make the nature of the suggestion self-evident or put additional information in the body of the comment, for example: 63

```

!topic [c]{C}haracter
!topic it["]s meaning is not defined

```

Formal requests for interpretations and for reporting defects in this International Standard may be made in accordance with the ISO/IEC JTC 1 Directives and the ISO/IEC JTC 1/SC 22 policy for interpretations. National Bodies may submit a Defect Report to ISO/IEC JTC 1/SC 22 for resolution under the JTC 1 procedures. A response will be provided and, if appropriate, a Technical Corrigendum will be issued in accordance with the procedures. 65

Acknowledgements for the Ada 83 edition

- 65.1/3 Ada is the result of a collective effort to design a common language for programming large scale and real-time systems.
- 65.2/3 The common high order language program began in 1974. The requirements of the United States Department of Defense were formalized in a series of documents which were extensively reviewed by the Services, industrial organizations, universities, and foreign military departments. The Ada language was designed in accordance with the final (1978) form of these requirements, embodied in the Steelman specification.
- 65.3/3 The Ada design team was led by Jean D. Ichbiah and has included Bernd Krieg-Brueckner, Brian A. Wichmann, Henry F. Ledgard, Jean-Claude Heliard, Jean-Loup Gailly, Jean-Raymond Abrial, John G.P. Barnes, Mike Woodger, Olivier Roubine, Paul N. Hilfinger, and Robert Firth.
- 65.4/3 At various stages of the project, several people closely associated with the design team made major contributions. They include J.B. Goodenough, R.F. Brender, M.W. Davis, G. Ferran, K. Lester, L. MacLaren, E. Morel, I.R. Nassi, I.C. Pyle, S.A. Schuman, and S.C. Vestal.
- 65.5/3 Two parallel efforts that were started in the second phase of this design had a deep influence on the language. One was the development of a formal definition using denotational semantics, with the participation of V. Donzeau-Gouge, G. Kahn, and B. Lang. The other was the design of a test translator with the participation of K. Ripken, P. Boullier, P. Cadiou, J. Holden, J.F. Hueras, R.G. Lange, and D.T. Cornhill. The entire effort benefitted from the dedicated assistance of Lyn Churchill and Marion Myers, and the effective technical support of B. Gravem, W.L. Heimerdinger, and P. Cleve. H.G. Schmitz served as program manager.
- 65.6/3 Over the five years spent on this project, several intense week-long design reviews were conducted, with the participation of P. Belmont, B. Brosgol, P. Cohen, R. Dewar, A. Evans, G. Fisher, H. Harte, A.L. Hisgen, P. Knueven, M. Kronental, N. Lomuto, E. Ploedereeder, G. Seegmueller, V. Stenning, D. Taffs, and also F. Belz, R. Converse, K. Correll, A.N. Habermann, J. Sammet, S. Squires, J. Teller, P. Wegner, and P.R. Wetherall.
- 65.7/3 Several persons had a constructive influence with their comments, criticisms and suggestions. They include P. Brinch Hansen, G. Goos, C.A.R. Hoare, Mark Rain, W.A. Wulf, and also E. Boebert, P. Bonnard, H. Clausen, M. Cox, G. Dismukes, R. Eachus, T. Froggatt, H. Ganzinger, C. Hewitt, S. Kamin, R. Kotler, O. Lecarme, J.A.N. Lee, J.L. Mansion, F. Minel, T. Phinney, J. Roehrich, V. Schneider, A. Singer, D. Slosberg, I.C. Wand, the reviewers of Ada-Europe, AdaTech, Afcet, those of the LMSC review team, and those of the Ada Tokyo Study Group.
- 65.8/3 These reviews and comments, the numerous evaluation reports received at the end of the first and second phase, the nine hundred language issue reports and test and evaluation reports received from fifteen different countries during the third phase of the project, the thousands of comments received during the ANSI Canvass, and the on-going work of the IFIP Working Group 2.4 on system implementation languages and that of the Purdue Europe LTPL-E committee, all had a substantial influence on the final definition of Ada.
- 65.9/3 The Military Departments and Agencies have provided a broad base of support including funding, extensive reviews, and countless individual contributions by the members of the High Order Language Working Group and other interested personnel. In particular, William A. Whitaker provided leadership for the program during the formative stages. David A. Fisher was responsible for the successful development and refinement of the language requirement documents that led to the Steelman specification.

The Ada 83 language definition was developed by Cii Honeywell Bull and later Alsys, and by Honeywell Systems and Research Center, under contract to the United States Department of Defense. William E. Carlson and later Larry E. Druffel served as the technical representatives of the United States Government and effectively coordinated the efforts of all participants in the Ada program. 65.10/3

Acknowledgements for the Ada 95 edition

This International Standard was prepared by the Ada 9X Mapping/Revision Team based at Intermetrics, Inc., which has included: W. Carlson, Program Manager; T. Taft, Technical Director; J. Barnes (consultant); B. Brosgol (consultant); R. Duff (Oak Tree Software); M. Edwards; C. Garrity; R. Hilliard; O. Pazy (consultant); D. Rosenfeld; L. Shafer; W. White; M. Woodger. 66

The following consultants to the Ada 9X Project contributed to the Specialized Needs Annexes: T. Baker (Real-Time/Systems Programming — SEI, FSU); K. Dritz (Numerics — Argonne National Laboratory); A. Gargaro (Distributed Systems — Computer Sciences); J. Goodenough (Real-Time/Systems Programming — SEI); J. McHugh (Secure Systems — consultant); B. Wichmann (Safety-Critical Systems — NPL: UK). 67

This work was regularly reviewed by the Ada 9X Distinguished Reviewers and the members of the Ada 9X Rapporteur Group (XRG): E. Ploedereder, Chairman of DRs and XRG (University of Stuttgart: Germany); B. Bardin (Hughes); J. Barnes (consultant: UK); B. Brett (DEC); B. Brosgol (consultant); R. Brukardt (RR Software); N. Cohen (IBM); R. Dewar (NYU); G. Dismukes (TeleSoft); A. Evans (consultant); A. Gargaro (Computer Sciences); M. Gerhardt (ESL); J. Goodenough (SEI); S. Heilbrunner (University of Salzburg: Austria); P. Hilfinger (UC/Berkeley); B. Källberg (CelsiusTech: Sweden); M. Kamrad II (Unisys); J. van Katwijk (Delft University of Technology: The Netherlands); V. Kaufman (Russia); P. Kruchten (Rational); R. Landwehr (CCI: Germany); C. Lester (Portsmouth Polytechnic: UK); L. Månsson (TELIA Research: Sweden); S. Michell (Multiprocessor Toolsmiths: Canada); M. Mills (US Air Force); D. Pogge (US Navy); K. Power (Boeing); O. Roubine (Verdix: France); A. Strohmeier (Swiss Fed Inst of Technology: Switzerland); W. Taylor (consultant: UK); J. Tokar (Tartan); E. Vasilescu (Grumman); J. Vladik (Prospeks s.r.o.: Czech Republic); S. Van Vlierberghe (OFFIS: Belgium). 68

Other valuable feedback influencing the revision process was provided by the Ada 9X Language Precision Team (Odyssey Research Associates), the Ada 9X User/Implementer Teams (AETECH, Tartan, TeleSoft), the Ada 9X Implementation Analysis Team (New York University) and the Ada community-at-large. 69

Special thanks go to R. Mathis, Convenor of ISO/IEC JTC 1/SC 22 Working Group 9. 70

The Ada 9X Project was sponsored by the Ada Joint Program Office. Christine M. Anderson at the Air Force Phillips Laboratory (Kirtland AFB, NM) was the project manager. 71

Acknowledgements for the Corrigendum version

The editor [R. Brukardt (USA)] would like to thank the many people whose hard work and assistance has made this update possible. 71.1/3

Thanks go out to all of the members of the ISO/IEC JTC 1/SC 22/WG 9 Ada Rapporteur Group, whose work on creating and editing the wording corrections was critical to the entire process. Especially valuable contributions came from the chairman of the ARG, E. Ploedereder (Germany), who kept the process moving; J. Barnes (UK) and K. Ishihata (Japan), whose extremely detailed reviews kept the editor on his toes; G. Dismukes (USA), M. Kamrad (USA), P. Leroy (France), S. Michell (Canada), T. Taft (USA), J. Tokar (USA), and other members too numerous to mention. 71.2/1

- 71.3/1 Special thanks go to R. Duff (USA) for his explanations of the previous system of formatting of these documents during the tedious conversion to more modern formats. Special thanks also go to the convenor of ISO/IEC JTC 1/SC 22/WG 9, J. Moore (USA), without whose help and support the Corrigendum and this consolidated reference manual would not have been possible.

Acknowledgements for the Amendment 1 version

- 71.4/3 The editor [R. Brukardt (USA)] would like to thank the many people whose hard work and assistance has made this update possible.
- 71.5/2 Thanks go out to all of the members of the ISO/IEC JTC 1/SC 22/WG 9 Ada Rapporteur Group, whose work on creating and editing the wording corrections was critical to the entire process. Especially valuable contributions came from the chairman of the ARG, P. Leroy (France), who kept the process on schedule; J. Barnes (UK) whose careful reviews found many typographical errors; T. Taft (USA), who always seemed to have a suggestion when we were stuck, and who also was usually able to provide the valuable service of explaining why things were as they are; S. Baird (USA), who found many obscure problems with the proposals; and A. Burns (UK), who pushed many of the real-time proposals to completion. Other ARG members who contributed were: R. Dewar (USA), G. Dismukes (USA), R. Duff (USA), K. Ishihata (Japan), S. Michell (Canada), E. Ploedereder (Germany), J.P. Rosen (France), E. Schonberg (USA), J. Tokar (USA), and T. Vardanega (Italy).
- 71.6/2 Special thanks go to Ada-Europe and the Ada Resource Association, without whose help and support the Amendment and this consolidated reference manual would not have been possible. M. Heaney (USA) requires special thanks for his tireless work on the containers packages. Finally, special thanks go to the convenor of ISO/IEC JTC 1/SC 22/WG 9, J. Moore (USA), who guided the document through the standardization process.

Acknowledgements for the Ada 2012 edition

- 71.7/3 The editor [R. Brukardt (USA)] would like to thank the many people whose hard work and assistance has made this revision possible.
- 71.8/3 Thanks go out to all of the members of the ISO/IEC JTC 1/SC 22/WG 9 Ada Rapporteur Group, whose work on creating and editing the wording changes was critical to the entire process. Especially valuable contributions came from the chairman of the ARG, E. Schonberg (USA), who guided the work; T. Taft (USA), whose insights broke many logjams, both in design and wording; J. Barnes (UK) whose careful reviews uncovered many editorial errors; S. Baird (USA), who repeatedly found obscure interactions with the proposals that the rest of us missed. Other ARG members who substantially contributed were: A. Burns (UK), J. Cousins (UK), R. Dewar (USA), G. Dismukes (USA), R. Duff (USA), P. Leroy (France), B. Moore (Canada), E. Ploedereder (Germany), J.P. Rosen (France), B. Thomas (USA), and T. Vardanega (Italy).
- 71.9/3 Special thanks go to Ada-Europe and the Ada Resource Association, without whose help and support this third edition of the Ada Standard would not have been possible. A special mention has to go to A. Benesch (USA) for his efforts in eliminating sloppiness in our wording. M. Heaney (USA) also deserves a mention for his efforts to improve the containers packages. Finally, special thanks go to the convenor of ISO/IEC JTC 1/SC 22/WG 9, J. Tokar (USA), who guided the document through the standardization process.

Changes

- The International Standard is the same as this version of the Reference Manual, except: 72
- This list of Changes is not included in the International Standard. 73
 - The “Acknowledgements” page is not included in the International Standard. 74
 - The text in the running headers and footers on each page is slightly different in the International Standard. 75
 - The title page(s) are different in the International Standard. 76
 - This document is formatted for 8.5-by-11-inch paper, whereas the International Standard is formatted for A4 paper (210-by-297mm); thus, the page breaks are in different places. 77
 - *This paragraph was deleted.* 77.1/3
 - {*AI05-0299-1*} The “Using this version of the Ada Reference Manual” subclause is not included in the International Standard. 77.2/3
 - Paragraph numbers are not included in the International Standard. 77.3/3

Using this version of the Ada Reference Manual

This document has been revised with the corrections specified in Technical Corrigendum 1 (ISO/IEC 8652:1995/COR.1:2001) and Amendment 1 (ISO/IEC 8652/AMD 1:2007), along with changes specifically for this third edition. In addition, more annotations have been added and a variety of editorial errors have been corrected. 77.4/3

Changes to the original 8652:1995 can be identified by the version number following the paragraph number. Paragraphs with a version number of /1 were changed by Technical Corrigendum 1 or were editorial corrections at that time, while paragraphs with a version number of /2 were changed by Amendment 1 or were more recent editorial corrections, and paragraphs with a version number of /3 were changed by the third (2012) edition of the Standard or were still more recent editorial corrections. Paragraphs not so marked are unchanged by the third edition, Amendment 1, Technical Corrigendum 1, or editorial corrections. Paragraph numbers of unchanged paragraphs are the same as in the 1995 edition of the Ada Reference Manual. Inserted text is indicated by underlining, and deleted text is indicated by strikethroughs. Some versions also use color to indicate the version of the change. Where paragraphs are inserted, the paragraph numbers are of the form pp.nn, where pp is the number of the preceding paragraph, and nn is an insertion number. For instance, the first paragraph inserted after paragraph 8 is numbered 8.1, the second paragraph inserted is numbered 8.2, and so on. Deleted paragraphs are indicated by the text *This paragraph was deleted*. Deleted paragraphs include empty paragraphs that were numbered in the 1995 edition of the Ada Reference Manual. Similar markings and numbering are used for changes to annotations. 77.5/3

To be honest: The paragraph number is considered part of the paragraph; when a paragraph is moved to a different paragraph number, it is marked as changed even if the contents have not changed. 77.a/3

1 General

- Discussion:** This Annotated Ada Reference Manual (AARM) contains the entire text of the third edition of the Ada Reference Manual (the Ada 2012 RM), plus certain annotations. The annotations give a more in-depth analysis of the language. They describe the reason for each nonobvious rule, and point out interesting ramifications of the rules and interactions among the rules (interesting to language lawyers, that is). Differences between Ada 83, Ada 95, Ada 2005, and Ada 2012 are listed. (The text you are reading now is an annotation.) 2.a/3
- The AARM stresses detailed correctness and uniformity over readability and understandability. We're not trying to make the language “appear” simple here; on the contrary, we're trying to expose hidden complexities, so we can more easily detect language bugs. The Ada 2012 RM, on the other hand, is intended to be a more readable document for programmers. 2.b/3
- The annotations in the AARM are as follows: 2.c
- Text that is logically redundant is shown [in square brackets, like this]. Technically, such text could be written as a Note in the Ada 2012 RM (and the Ada 95 and 2005 RMs before it), since it is really a theorem that can be proven from the nonredundant rules of the language. We use the square brackets instead when it seems to make the Ada 2012 RM more readable. 2.d/3
 - The rules of the language (and some AARM-only text) are categorized, and placed under certain *sub-headings* that indicate the category. For example, the distinction between Name Resolution Rules and Legality Rules is particularly important, as explained in 8.6. 2.e
 - Text under the following sub-headings appears in both documents: 2.f
 - The unlabeled text at the beginning of each clause or subclause, 2.g
 - Syntax, 2.h
 - Name Resolution Rules, 2.i
 - Legality Rules, 2.j
 - Static Semantics, 2.k
 - Post-Compilation Rules, 2.l
 - Dynamic Semantics, 2.m
 - Bounded (Run-Time) Errors, 2.n
 - Erroneous Execution, 2.o
 - Implementation Requirements, 2.p
 - Documentation Requirements, 2.q
 - Metrics, 2.r
 - Implementation Permissions, 2.s
 - Implementation Advice, 2.t
 - NOTES, 2.u
 - Examples. 2.v
 - Text under the following sub-headings does not appear in the Ada 2012 RM: 2.w/3
 - Language Design Principles, 2.x
 - Inconsistencies With Ada 83, 2.y
 - Incompatibilities With Ada 83, 2.z
 - Extensions to Ada 83, 2.aa
 - Wording Changes from Ada 83, 2.bb/2
 - Inconsistencies With Ada 95, 2.bb.1/2
 - Incompatibilities With Ada 95, 2.bb.2/2
 - Extensions to Ada 95, 2.bb.3/2
 - Wording Changes from Ada 95, 2.bb.4/3
 - Inconsistencies With Ada 2005, 2.bb.5/3
 - Incompatibilities With Ada 2005, 2.bb.6/3

- 2.bb.7/3 • Extensions to Ada 2005,
- 2.bb.8/3 • Wording Changes from Ada 2005.
- 2.cc • The AARM also includes the following kinds of annotations. These do not necessarily annotate the immediately preceding rule, although they often do.
- 2.dd **Reason:** An explanation of why a certain rule is necessary, or why it is worded in a certain way.
- 2.ee **Ramification:** An obscure ramification of the rules that is of interest only to language lawyers. (If a ramification of the rules is of interest to programmers, then it appears under NOTES.)
- 2.ff **Proof:** An informal proof explaining how a given Note or [marked-as-redundant] piece of text follows from the other rules of the language.
- 2.gg **Implementation Note:** A hint about how to implement a feature, or a particular potential pitfall that an implementer needs to be aware of.
- 2.hh **Change:** Change annotations are not used in this version. Changes from previous versions have been removed. Changes in this version are marked with versioned paragraph numbers, as explained in the “Corrigendum Changes” clause of the “Introduction”.
- 2.ii **Discussion:** Other annotations not covered by the above.
- 2.jj **To be honest:** A rule that is considered logically necessary to the definition of the language, but which is so obscure or pedantic that only a language lawyer would care. These are the only annotations that could be considered part of the language definition.
- 2.kk **Glossary entry:** The text of a Glossary entry — this text will also appear in Annex N, “Glossary”.
- 2.ll/3 **Discussion:** In general, the Ada 2012 RM text appears in the normal font, whereas AARM-only text appears in a smaller font. Notes also appear in the smaller font, as recommended by ISO/IEC style guidelines. Ada examples are also usually printed in a smaller font.
- 2.mm If you have trouble finding things, be sure to use the index. Each defined term appears there, and also in *italics*, like *this*. Syntactic categories defined in BNF are also indexed.
- 2.nn A definition marked “[distributed]” is the main definition for a term whose complete definition is given in pieces distributed throughout the document. The pieces are marked “[partial]” or with a phrase explaining what cases the partial definition applies to.

1.1 Scope

- 1/3 {AI05-0299-1} This International Standard specifies the form and meaning of programs written in Ada. Its purpose is to promote the portability of Ada programs to a variety of computing systems.
- 2/3 {AI05-0299-1} Ada is a programming language designed to support the construction of long-lived, highly reliable software systems. The language includes facilities to define packages of related types, objects, and operations. The packages may be parameterized and the types may be extended to support the construction of libraries of reusable, adaptable software components. The operations may be implemented as subprograms using conventional sequential control structures, or as entries that include synchronization of concurrent threads of control as part of their invocation. Ada supports object-oriented programming by providing classes and interfaces, inheritance, polymorphism of variables and methods, and generic units. The language treats modularity in the physical sense as well, with a facility to support separate compilation.
- 3/3 {AI05-0269-1} {AI05-0299-1} The language provides rich support for real-time, concurrent programming, and includes facilities for multicore and multiprocessor programming. Errors can be signaled as exceptions and handled explicitly. The language also covers systems programming; this requires precise control over the representation of data and access to system-dependent properties. Finally, a predefined environment of standard packages is provided, including facilities for, among others, input-output, string manipulation, numeric elementary functions, and random number generation, and definition and use of containers.

1.1.1 Extent

This International Standard specifies:

- The form of a program written in Ada; 1
- The effect of translating and executing such a program; 2
- The manner in which program units may be combined to form Ada programs; 3
- The language-defined library units that a conforming implementation is required to supply; 4
- The permissible variations within the standard, and the manner in which they are to be documented; 5
- Those violations of the standard that a conforming implementation is required to detect, and the effect of attempting to translate or execute a program containing such violations; 6
- Those violations of the standard that a conforming implementation is not required to detect. 7

This International Standard does not specify:

- The means whereby a program written in Ada is transformed into object code executable by a processor; 9
- The means whereby translation or execution of programs is invoked and the executing units are controlled; 10
- The size or speed of the object code, or the relative execution speed of different language constructs; 11
- The form or contents of any listings produced by implementations; in particular, the form or contents of error or warning messages; 12
- The effect of unspecified execution. 13
- The size of a program or program unit that will exceed the capacity of a particular conforming implementation. 14

1.1.2 Structure

{AI05-0299-1} This International Standard contains thirteen clauses, fifteen annexes, and an index. 1/3

Discussion: {AI05-0299-1} What Ada 83 called a “chapter” and Ada 95 (and Ada 2005) called a “section” is called a “clause” in this Standard. Similarly, what Ada 83 called a “section” and Ada 95 (and Ada 2005) called a “clause” is called a “subclause” in this Standard. Confused yet? This terminology is out of our hands; it is (and was) forced by ever-changing ISO rules for drafting Standards. 1.a/3

The *core* of the Ada language consists of: 2

- {AI05-0299-1} Clauses 1 through 13 3/3
- Annex A, “Predefined Language Environment” 4
- Annex B, “Interface to Other Languages” 5
- Annex J, “Obsolescent Features” 6

The following *Specialized Needs Annexes* define features that are needed by certain application areas: 7

- Annex C, “Systems Programming” 8
- Annex D, “Real-Time Systems” 9
- Annex E, “Distributed Systems” 10

- 11 • Annex F, “Information Systems”
- 12 • Annex G, “Numerics”
- 13 • Annex H, “High Integrity Systems”

14 The core language and the Specialized Needs Annexes are normative, except that the material in each of the items listed below is informative:

- 15 • Text under a NOTES or Examples heading.
- 16/3 • {AI05-0299-1} Each subclause whose title starts with the word “Example” or “Examples”.

17 All implementations shall conform to the core language. In addition, an implementation may conform separately to one or more Specialized Needs Annexes.

18 The following Annexes are informative:

- 19 • Annex K, “Language-Defined Aspects and Attributes”
- 20 • Annex L, “Language-Defined Pragmas”
- 21/3 • {AI05-0004-1} Annex M, “Summary of Documentation Requirements”
- 22 • Annex N, “Glossary”
- 23 • Annex P, “Syntax Summary”
- 23.1/3 • {AI05-0262-1} Annex Q, “Language-Defined Entities”

23.a **Discussion:** The idea of the Specialized Needs Annexes is that implementations can choose to target certain application areas. For example, an implementation specifically targeted to embedded machines might support the application-specific features for Real-time Systems, but not the application-specific features for Information Systems.

23.b The Specialized Needs Annexes extend the core language only in ways that users, implementations, and standards bodies are allowed to extend the language; for example, via additional library units, attributes, representation items (see 13.1), pragmas, and constraints on semantic details that are left unspecified by the core language. Many implementations already provide much of the functionality defined by Specialized Needs Annexes; our goal is to increase uniformity among implementations by defining standard ways of providing the functionality.

23.c/2 {AI95-00114-01} We recommend that the certification procedures allow implementations to certify the core language, plus any set of the Specialized Needs Annexes. We recommend that implementations *not* be allowed to certify a portion of one of the Specialized Needs Annexes, although implementations can, of course, provide uncertified support for such portions. We have designed the Specialized Needs Annexes assuming that this recommendation is followed. Thus, our decisions about what to include and what not to include in those annexes are based on the assumption that each annex is certified in an “all-or-nothing” manner.

23.d An implementation may, of course, support extensions that are different from (but possibly related to) those defined by one of the Specialized Needs Annexes. We recommend that, where appropriate, implementations do this by adding library units that are children of existing language-defined library packages.

23.e An implementation should not provide extensions that conflict with those defined in the Specialized Needs Annexes, in the following sense: Suppose an implementation supports a certain error-free program that uses only functionality defined in the core and in the Specialized Needs Annexes. The implementation should ensure that that program will still be error free in some possible full implementation of all of the Specialized Needs Annexes, and that the semantics of the program will not change. For example, an implementation should not provide a package with the same name as one defined in one of the Specialized Needs Annexes, but that behaves differently, *even if that implementation does not claim conformance to that Annex*.

23.f Note that the Specialized Needs Annexes do not conflict with each other; it is the intent that a single implementation can conform to all of them.

24/3 {AI05-0299-1} Each section is divided into subclauses that have a common structure. Each clause and subclause first introduces its subject. After the introductory text, text is labeled with the following headings:

Language Design Principles

These are not rules of the language, but guiding principles or goals used in defining the rules of the language. In some cases, the goal is only partially met; such cases are explained. 24.a

{AI05-0005-1} This is not part of the definition of the language, and does not appear in the Ada 2012 RM. 24.b/3

Syntax

Syntax rules (indented). 25

Name Resolution Rules

{AI05-0299-1} Compile-time rules that are used in name resolution, including overload resolution. 26/3

Discussion: These rules are observed at compile time. (We say “observed” rather than “checked,” because these rules are not individually checked. They are really just part of the Legality Rules in Clause 8 that require exactly one interpretation of each constituent of a complete context.) The only rules used in overload resolution are the Syntax Rules and the Name Resolution Rules. 26.a

When dealing with nonoverloadable declarations it sometimes makes no semantic difference whether a given rule is a Name Resolution Rule or a Legality Rule, and it is sometimes difficult to decide which it should be. We generally make a given rule a Name Resolution Rule only if it has to be. For example, “The name, if any, in a `raise_statement` shall be the name of an exception.” is under “Legality Rules.” 26.b

Legality Rules

Rules that are enforced at compile time. A construct is *legal* if it obeys all of the Legality Rules. 27

Discussion: These rules are not used in overload resolution. 27.a

Note that run-time errors are always attached to exceptions; for example, it is not “illegal” to divide by zero, it just raises an exception. 27.b

Static Semantics

A definition of the compile-time effect of each construct. 28

Discussion: The most important compile-time effects represent the effects on the symbol table associated with declarations (implicit or explicit). In addition, we use this heading as a bit of a grab bag for equivalences, package specifications, etc. For example, this is where we put statements like so-and-so is equivalent to such-and-such. (We ought to try to really mean it when we say such things!) Similarly, statements about magically-generated implicit declarations go here. These rules are generally written as statements of fact about the semantics, rather than as a you-shall-do-such-and-such sort of thing. 28.a

Post-Compilation Rules

Rules that are enforced before running a partition. A partition is legal if its compilation units are legal and it obeys all of the Post-Compilation Rules. 29

Discussion: It is not specified exactly when these rules are checked, so long as they are checked for any given partition before that partition starts running. An implementation may choose to check some such rules at compile time, and reject `compilation_units` accordingly. Alternatively, an implementation may check such rules when the partition is created (usually known as “link time”), or when the partition is mapped to a particular piece of hardware (but before the partition starts running). 29.a

Dynamic Semantics

A definition of the run-time effect of each construct. 30

Discussion: This heading describes what happens at run time. Run-time checks, which raise exceptions upon failure, are described here. Each item that involves a run-time check is marked with the name of the check — these are the same check names that are used in a `pragma Suppress`. Principle: Every check should have a name, usable in a `pragma Suppress`. 30.a

Bounded (Run-Time) Errors

Situations that result in bounded (run-time) errors (see 1.1.5). 31

31.a **Discussion:** The “bounds” of each such error are described here — that is, we characterize the set of all possible behaviors that can result from a bounded error occurring at run time.

Erroneous Execution

32 Situations that result in erroneous execution (see 1.1.5).

Implementation Requirements

33 Additional requirements for conforming implementations.

33.a **Discussion:** ...as opposed to rules imposed on the programmer. An example might be, “The smallest representable duration, `Duration'Small`, shall not be greater than twenty milliseconds.”

33.b It's really just an issue of how the rule is worded. We could write the same rule as “The smallest representable duration is an implementation-defined value less than or equal to 20 milliseconds” and then it would be under “Static Semantics.”

Documentation Requirements

34 Documentation requirements for conforming implementations.

34.a **Discussion:** These requirements are beyond those that are implicitly specified by the phrase “implementation defined”. The latter require documentation as well, but we don't repeat these cases under this heading. Usually this heading is used for when the description of the documentation requirement is longer and does not correspond directly to one, narrow normative sentence.

Metrics

35 Metrics that are specified for the time/space properties of the execution of certain language constructs.

Implementation Permissions

36 Additional permissions given to the implementer.

36.a **Discussion:** For example, “The implementation is allowed to impose further restrictions on the record aggregates allowed in code statements.” When there are restrictions on the permission, those restrictions are given here also. For example, “An implementation is allowed to restrict the kinds of subprograms that are allowed to be main subprograms. However, it shall support at least parameterless procedures.” — we don't split this up between here and “Implementation Requirements.”

Implementation Advice

37 Optional advice given to the implementer. The word “should” is used to indicate that the advice is a recommendation, not a requirement. It is implementation defined whether or not a given recommendation is obeyed.

37.a/2 **Implementation defined:** Whether or not each recommendation given in Implementation Advice is followed — see M.3, “Implementation Advice” for a listing.

37.b/1 **Discussion:** The advice generally shows the intended implementation, but the implementer is free to ignore it. The implementer is the sole arbiter of whether or not the advice has been obeyed, if not, whether the reason is a good one, and whether the required documentation is sufficient. It would be wrong for the ACATS to enforce any of this advice.

37.c For example, “Whenever possible, the implementation should choose a value no greater than fifty microseconds for the smallest representable duration, `Duration'Small`.”

37.d We use this heading, for example, when the rule is so low level or implementation-oriented as to be untestable. We also use this heading when we wish to encourage implementations to behave in a certain way in most cases, but we do not wish to burden implementations by requiring the behavior.

NOTES

38 1 Notes emphasize consequences of the rules described in the (sub)clause or elsewhere. This material is informative.

Examples

39 Examples illustrate the possible forms of the constructs described. This material is informative.

39.a **Discussion:**

The next three headings list all language changes between Ada 83 and Ada 95. Language changes are any change that changes the set of text strings that are legal Ada programs, or changes the meaning of any legal program. Wording changes, such as changes in terminology, are not language changes. Each language change falls into one of the following three categories:

Inconsistencies With Ada 83

This heading lists all of the upward inconsistencies between Ada 83 and Ada 95. Upward inconsistencies are situations in which a legal Ada 83 program is a legal Ada 95 program with different semantics. This type of upward incompatibility is the worst type for users, so we only tolerate it in rare situations. 39.b

(Note that the semantics of a program is not the same thing as the behavior of the program. Because of Ada's indeterminacy, the “semantics” of a given feature describes a *set* of behaviors that can be exhibited by that feature. The set can contain more than one allowed behavior. Thus, when we ask whether the semantics changes, we are asking whether the set of behaviors changes.) 39.c

This is not part of the definition of the language, and does not appear in the Ada 95, Ada 2005, or Ada 2012 RM. 39.d/3

Incompatibilities With Ada 83

This heading lists all of the upward incompatibilities between Ada 83 and Ada 95, except for the ones listed under “Inconsistencies With Ada 83” above. These are the situations in which a legal Ada 83 program is illegal in Ada 95. We do not generally consider a change that turns erroneous execution into an exception, or into an illegality, to be upwardly incompatible. 39.e

This is not part of the definition of the language, and does not appear in the Ada 95, Ada 2005, or Ada 2012 RM. 39.f/3

Extensions to Ada 83

This heading is used to list all upward compatible language changes; that is, language extensions. These are the situations in which a legal Ada 95 program is not a legal Ada 83 program. The vast majority of language changes fall into this category. 39.g

This is not part of the definition of the language, and does not appear in the Ada 95, Ada 2005, or Ada 2012 RM. 39.h/3
39.i

As explained above, the next heading does not represent any language change:

Wording Changes from Ada 83

This heading lists some of the nonsemantic changes between the Ada 83 RM and the Ada 95 RM. It is incomplete; we have not attempted to list all wording changes, but only the “interesting” ones. 39.j/2

This is not part of the definition of the language, and does not appear in the Ada 95, Ada 2005, or Ada 2012 RM. 39.k/3

Discussion: 39.l/2

The next three headings list all language changes between Ada 95 and Ada 2005 (the language defined by the Ada 95 standard plus Technical Corrigendum 1 plus Amendment 1). Each language change falls into one of the following three categories:

Inconsistencies With Ada 95

This heading lists all of the upward inconsistencies between Ada 95 and Ada 2005. Upward inconsistencies are situations in which a legal Ada 95 program is a legal Ada 2005 program with different semantics. 39.m/2

{A105-0005-1} Inconsistencies marked with **Corrigendum:** are corrections to the original Ada 95 definition introduced by Corrigendum 1. Inconsistencies marked with **Amendment Correction:** are corrections to the original Ada 95 definition added by Amendment 1. Formally, these are inconsistencies caused by Ada Issues classified as Binding Interpretations; implementations of Ada 95 are supposed to follow these corrections, not the original flawed language definition. Thus, these strictly speaking are not inconsistencies between Ada 95 and Ada 2005. Practically, however, they very well may be, as early Ada 95 implementations might not follow the recommendation. Inconsistencies so marked are not portable between Ada 95 implementations, while usually Ada 2005 will have more clearly defined behavior. Therefore, we document these for completeness. 39.n/3

This is not part of the definition of the language, and does not appear in the Ada 2005 or Ada 2012 RM. 39.o/3

Incompatibilities With Ada 95

- 39.p/2 This heading lists all of the upward incompatibilities between Ada 95 and Ada 2005, except for the ones listed under “Inconsistencies With Ada 95” above. These are the situations in which a legal Ada 95 program is illegal in Ada 2005.
- 39.q/3 {*AI05-0005-1*} As with inconsistencies, incompatibilities marked with **Corrigendum**: are corrections to the original Ada 95 definition introduced by Corrigendum 1. Incompatibilities marked with **Amendment Correction**: are corrections to the original Ada 95 definition added by Amendment 1. Formally, these are incompatibilities caused by Ada Issues classified as Binding Interpretations; implementations of Ada 95 are supposed to follow these corrections, not the original flawed language definition. Thus, these strictly speaking are not incompatibilities between Ada 95 and Ada 2005. Practically, however, they very well may be, as early Ada 95 implementations might not follow the recommendation. Therefore, some Ada 95 implementations may be able to compile the examples, while others might not. In contrast, Ada 2005 compilers will have consistent behavior. Therefore, we document these for completeness.
- 39.r/3 This is not part of the definition of the language, and does not appear in the Ada 2005 or Ada 2012 RM.

Extensions to Ada 95

- 39.s/2 This heading is used to list all upward compatible language changes; that is, language extensions. These are the situations in which a legal Ada 2005 program is not a legal Ada 95 program. The vast majority of language changes fall into this category.
- 39.t/3 {*AI05-0005-1*} As with incompatibilities, extensions marked with **Corrigendum**: are corrections to the original Ada 95 definition introduced by Corrigendum 1. Extensions marked with **Amendment Correction**: are corrections to the original Ada 95 definition added by Amendment 1. Formally, these are extensions allowed by Ada Issues classified as Binding Interpretations. As corrections, implementations of Ada 95 are allowed to implement these extensions. Thus, these strictly speaking are not extensions of Ada 95; they're part of Ada 95. Practically, however, they very well may be extensions, as early Ada 95 implementations might not implement the extension. Therefore, some Ada 95 implementations may be able to compile the examples, while others might not. In contrast, Ada 2005 compilers will always support the extensions. Therefore, we document these for completeness.
- 39.u/3 This is not part of the definition of the language, and does not appear in the Ada 2005 or Ada 2012 RM.

39.v/2

As explained above, the next heading does not represent any language change:

Wording Changes from Ada 95

- 39.w/2 This heading lists some of the nonsemantic changes between the Ada 95 RM and the Ada 2005 RM. This heading lists only “interesting” changes (for instance, editorial corrections are not listed). Changes which come from Technical Corrigendum 1 are marked **Corrigendum**; unmarked changes come from Amendment 1.
- 39.x/3 This is not part of the definition of the language, and does not appear in the Ada 2005 or Ada 2012 RM.

39.y/3 **Discussion:**

The next three headings list all language changes between Ada 2005 (the language defined by the Ada 95 standard plus Technical Corrigendum 1 plus Amendment 1) and Ada 2012 (the language defined by the third edition of the Standard). Each language change falls into one of the following three categories:

Inconsistencies With Ada 2005

- 39.z/3 This heading lists all of the upward inconsistencies between Ada 2005 and Ada 2012. Upward inconsistencies are situations in which a legal Ada 2005 program is a legal Ada 2012 program with different semantics.
- 39.aa/3 Inconsistencies marked with **Correction**: are corrections to the original Ada 2005 definition added by the third edition of the Standard. Formally, these are inconsistencies caused by Ada Issues classified as Binding Interpretations; implementations of Ada 2005 are supposed to follow these corrections, not the original flawed language definition. Thus, these strictly speaking are not inconsistencies between Ada 2005 and Ada 2012. Practically, however, they very well may be, as early Ada 2005 implementations might not follow the recommendation. Inconsistencies so marked are not portable between Ada 2005 implementations, while usually Ada 2012 will have more clearly defined behavior. Therefore, we document these for completeness.
- 39.bb/3 This is not part of the definition of the language, and does not appear in the Ada 2012 RM.

Incompatibilities With Ada 2005

- 39.cc/3 This heading lists all of the upward incompatibilities between Ada 2005 and Ada 2012, except for the ones listed under “Inconsistencies With Ada 2005” above. These are the situations in which a legal Ada 2005 program is illegal in Ada 2012.

As with inconsistencies, incompatibilities marked with **Correction:** are corrections to the original Ada 2005 definition added by the third edition. Formally, these are incompatibilities caused by Ada Issues classified as Binding Interpretations; implementations of Ada 2005 are supposed to follow these corrections, not the original flawed language definition. Thus, these strictly speaking are not incompatibilities between Ada 2005 and Ada 2012. Practically, however, they very well may be, as early Ada 2005 implementations might not follow the recommendation. Therefore, some Ada 2005 implementations may be able to compile the examples, while others might not. In contrast, Ada 2012 compilers will have consistent behavior. Therefore, we document these for completeness. 39.dd/3

This is not part of the definition of the language, and does not appear in the Ada 2012 RM. 39.ee/3

Extensions to Ada 2005

This heading is used to list all upward compatible language changes; that is, language extensions. These are the situations in which a legal Ada 2012 program is not a legal Ada 2005 program. The vast majority of language changes fall into this category. 39.ff/3

As with incompatibilities, extensions marked with **Correction:** are corrections to the original Ada 2005 definition added by the third edition. Formally, these are extensions allowed by Ada Issues classified as Binding Interpretations. As corrections, implementations of Ada 2005 (and sometimes Ada 95) are allowed to implement these extensions. Thus, these strictly speaking are not extensions of Ada 2005; they're part of Ada 2005. Practically, however, they very well may be extensions, as early Ada 2005 implementations might not implement the extension. Therefore, some Ada 2005 implementations may be able to compile the examples, while others might not. In contrast, Ada 2012 compilers will always support the extensions. Therefore, we document these for completeness. 39.gg/3

This is not part of the definition of the language, and does not appear in the Ada 2012 RM. 39.hh/3

39.ii/3

As explained above, the next heading does not represent any language change:

Wording Changes from Ada 2005

This heading lists some of the nonsemantic changes between the Ada 2005 RM and the Ada 2012 RM. This heading lists only “interesting” changes (for instance, editorial corrections are not listed). Items marked **Correction:** come from Ada Issues classified as Binding Interpretations and strictly speaking belong to Ada 2005; other items only belong to Ada 2012. 39.jj/3

This is not part of the definition of the language, and does not appear in the Ada 2012 RM. 39.kk/3

1.1.3 Conformity of an Implementation with the Standard

Implementation Requirements

A conforming implementation shall: 1

Discussion: The *implementation* is the software and hardware that implements the language. This includes compiler, linker, operating system, hardware, etc. 1.a

We first define what it means to “conform” in general — basically, the implementation has to properly implement the normative rules given throughout the standard. Then we define what it means to conform to a Specialized Needs Annex — the implementation must support the core features plus the features of that Annex. Finally, we define what it means to “conform to the Standard” — this requires support for the core language, and allows partial (but not conflicting) support for the Specialized Needs Annexes. 1.b

- Translate and correctly execute legal programs written in Ada, provided that they are not so large as to exceed the capacity of the implementation; 2

- Identify all programs or program units that are so large as to exceed the capacity of the implementation (or raise an appropriate exception at run time); 3

Implementation defined: Capacity limitations of the implementation. 3.a

- Identify all programs or program units that contain errors whose detection is required by this International Standard; 4

Discussion: Note that we no longer use the term “rejection” of programs or program units. We require that programs or program units with errors or that exceed some capacity limit be “identified”. The way in which errors or capacity problems are reported is not specified. 4.a

4.b An implementation is allowed to use standard error-recovery techniques. We do not disallow such techniques from being used across `compilation_unit` or `compilation` boundaries.

4.c See also the Implementation Requirements of 10.2, which disallow the execution of illegal partitions.

- 5 • Supply all language-defined library units required by this International Standard;

5.a **Implementation Note:** An implementation cannot add to or modify the visible part of a language-defined library unit, except where such permission is explicitly granted, unless such modifications are semantically neutral with respect to the client compilation units of the library unit. An implementation defines the contents of the private part and body of language-defined library units.

5.b An implementation can add `with_clauses` and `use_clauses`, since these modifications are semantically neutral to clients. (The implementation might need `with_clauses` in order to implement the private part, for example.) Similarly, an implementation can add a private part even in cases where a private part is not shown in the standard. Explicit declarations can be provided implicitly or by renaming, provided the changes are semantically neutral.

5.c Wherever in the standard the text of a language-defined library unit contains an italicized phrase starting with “*implementation-defined*”, the implementation's version will replace that phrase with some implementation-defined text that is syntactically legal at that place, and follows any other applicable rules.

5.d Note that modifications are permitted, even if there are other tools in the environment that can detect the changes (such as a program library browser), so long as the modifications make no difference with respect to the static or dynamic semantics of the resulting programs, as defined by the standard.

- 6 • Contain no variations except those explicitly permitted by this International Standard, or those that are impossible or impractical to avoid given the implementation's execution environment;

6.a **Implementation defined:** Variations from the standard that are impractical to avoid given the implementation's execution environment.

6.b **Reason:** The “impossible or impractical” wording comes from AI-325. It takes some judgement and common sense to interpret this. Restricting compilation units to less than 4 lines is probably unreasonable, whereas restricting them to less than 4 billion lines is probably reasonable (at least given today's technology). We do not know exactly where to draw the line, so we have to make the rule vague.

- 7 • Specify all such variations in the manner prescribed by this International Standard.

8 The *external effect* of the execution of an Ada program is defined in terms of its interactions with its external environment. The following are defined as *external interactions*:

- 9 • Any interaction with an external file (see A.7);
- 10 • The execution of certain `code_statements` (see 13.8); which `code_statements` cause external interactions is implementation defined.

10.a **Implementation defined:** Which `code_statements` cause external interactions.

- 11 • Any call on an imported subprogram (see Annex B), including any parameters passed to it;
- 12 • Any result returned or exception propagated from a main subprogram (see 10.2) or an exported subprogram (see Annex B) to an external caller;

12.a **Discussion:** By “result returned” we mean to include function results and values returned in **[in] out** parameters.

12.a.1/1 {8652/0094} {A195-00119-01} The lack of a result from a program that does not terminate is also included here.

- 13 • [Any read or update of an atomic or volatile object (see C.6);]
- 14 • The values of imported and exported objects (see Annex B) at the time of any other interaction with the external environment.

14.a/3 **To be honest:** {A105-0229-1} Also other uses of imported and exported entities, as defined by the implementation, if the implementation supports such importing or exporting.

15 A conforming implementation of this International Standard shall produce for the execution of a given Ada program a set of interactions with the external environment whose order and timing are consistent with the definitions and requirements of this International Standard for the semantics of the given program.

- Ramification:** There is no need to produce any of the “internal effects” defined for the semantics of the program — all of these can be optimized away — so long as an appropriate sequence of external interactions is produced. 15.a
- Discussion:** See also 11.6 which specifies various liberties associated with optimizations in the presence of language-defined checks, that could change the external effects that might be produced. These alternative external effects are still consistent with the standard, since 11.6 is part of the standard. 15.b
- Note also that we only require “*an appropriate* sequence of external interactions” rather than “*the same* sequence...” An optimizer may cause a different sequence of external interactions to be produced than would be produced without the optimizer, so long as the new sequence still satisfies the requirements of the standard. For example, optimization might affect the relative rate of progress of two concurrent tasks, thereby altering the order in which two external interactions occur. 15.c
- Note that the Ada 83 RM explicitly mentions the case of an “exact effect” of a program, but since so few programs have their effects defined that exactly, we don’t even mention this “special” case. In particular, almost any program that uses floating point or tasking has to have some level of inexactness in the specification of its effects. And if one includes aspects of the timing of the external interactions in the external effect of the program (as is appropriate for a real-time language), no “exact effect” can be specified. For example, if two external interactions initiated by a single task are separated by a “**delay** 1.0;” then the language rules imply that the two external interactions have to be separated in time by at least one second, as defined by the clock associated with the `delay_relative_statement`. This in turn implies that the time at which an external interaction occurs is part of the characterization of the external interaction, at least in some cases, again making the specification of the required “exact effect” impractical. 15.d/2
- An implementation that conforms to this Standard shall support each capability required by the core language as specified. In addition, an implementation that conforms to this Standard may conform to one or more Specialized Needs Annexes (or to none). Conformance to a Specialized Needs Annex means that each capability required by the Annex is provided as specified. 16
- Discussion:** The last sentence defines what it means to say that an implementation conforms to a Specialized Needs Annex, namely, only by supporting all capabilities required by the Annex. 16.a
- {*AI05-0229-1*} An implementation conforming to this International Standard may provide additional aspects, attributes, library units, and pragmas. However, it shall not provide any aspect, attribute, library unit, or pragma having the same name as an aspect, attribute, library unit, or pragma (respectively) specified in a Specialized Needs Annex unless the provided construct is either as specified in the Specialized Needs Annex or is more limited in capability than that required by the Annex. A program that attempts to use an unsupported capability of an Annex shall either be identified by the implementation before run time or shall raise an exception at run time. 17/3
- Discussion:** The last sentence of the preceding paragraph defines what an implementation is allowed to do when it does not “conform” to a Specialized Needs Annex. In particular, the sentence forbids implementations from providing a construct with the same name as a corresponding construct in a Specialized Needs Annex but with a different syntax (e.g., an extended syntax) or quite different semantics. The phrase concerning “more limited in capability” is intended to give permission to provide a partial implementation, such as not implementing a subprogram in a package or having a restriction not permitted by an implementation that conforms to the Annex. For example, a partial implementation of the package `Ada.Decimal` might have `Decimal.Max_Decimal_Digits` as 15 (rather than the required 18). This allows a partial implementation to grow to a fully conforming implementation. 17.a
- A restricted implementation might be restricted by not providing some subprograms specified in one of the packages defined by an Annex. In this case, a program that tries to use the missing subprogram will usually fail to compile. Alternatively, the implementation might declare the subprogram as abstract, so it cannot be called. Alternatively, a subprogram body might be implemented just to raise `Program_Error`. The advantage of this approach is that a program to be run under a fully conforming Annex implementation can be checked syntactically and semantically under an implementation that only partially supports the Annex. Finally, an implementation might provide a package declaration without the corresponding body, so that programs can be compiled, but partitions cannot be built and executed. 17.b
- To ensure against wrong answers being delivered by a partial implementation, implementers are required to raise an exception when a program attempts to use an unsupported capability and this can be detected only at run time. For example, a partial implementation of `Ada.Decimal` might require the length of the `Currency` string to be 1, and hence, an exception would be raised if a subprogram were called in the package `Edited_Output` with a length greater than 1. 17.c
- Documentation Requirements*
- Certain aspects of the semantics are defined to be either *implementation defined* or *unspecified*. In such cases, the set of possible effects is specified, and the implementation may choose any effect in the set. 18

Implementations shall document their behavior in implementation-defined situations, but documentation is not required for unspecified situations. The implementation-defined characteristics are summarized in M.2.

- 18.a **Discussion:** We used to use the term “implementation dependent” instead of “unspecified”. However, that sounded too much like “implementation defined”. Furthermore, the term “unspecified” is used in the ANSI C and POSIX standards for this purpose, so that is another advantage. We also use “not specified” and “not specified by the language” as synonyms for “unspecified.” The documentation requirement is the only difference between implementation defined and unspecified.
- 18.b Note that the “set of possible effects” can be “all imaginable effects”, as is the case with erroneous execution.
- 19 The implementation may choose to document implementation-defined behavior either by documenting what happens in general, or by providing some mechanism for the user to determine what happens in a particular case.
- 19.a **Discussion:** For example, if the standard says that library unit elaboration order is implementation defined, the implementation might describe (in its user's manual) the algorithm it uses to determine the elaboration order. On the other hand, the implementation might provide a command that produces a description of the elaboration order for a partition upon request from the user. It is also acceptable to provide cross references to existing documentation (for example, a hardware manual), where appropriate.
- 19.b Note that dependence of a program on implementation-defined or unspecified functionality is not defined to be an error; it might cause the program to be less portable, however.
- 19.c/2 **Documentation Requirement:** The behavior of implementations in implementation-defined situations shall be documented — see M.2, “Implementation-Defined Characteristics” for a listing.

Implementation Advice

- 20 If an implementation detects the use of an unsupported Specialized Needs Annex feature at run time, it should raise Program_Error if feasible.
- 20.a.1/2 **Implementation Advice:** Program_Error should be raised when an unsupported Specialized Needs Annex feature is used at run time.
- 20.a **Reason:** The reason we don't *require* Program_Error is that there are situations where other exceptions might make sense. For example, if the Real Time Systems Annex requires that the range of System.Priority include at least 30 values, an implementation could conform to the Standard (but not to the Annex) if it supported only 12 values. Since the rules of the language require Constraint_Error to be raised for out-of-range values, we cannot require Program_Error to be raised instead.
- 21 If an implementation wishes to provide implementation-defined extensions to the functionality of a language-defined library unit, it should normally do so by adding children to the library unit.
- 21.a.1/2 **Implementation Advice:** Implementation-defined extensions to the functionality of a language-defined library unit should be provided by adding children to the library unit.
- 21.a **Implementation Note:** If an implementation has support code (“run-time system code”) that is needed for the execution of user-defined code, it can put that support code in child packages of System. Otherwise, it has to use some trick to avoid polluting the user's namespace. It is important that such tricks not be available to user-defined code (not in the standard mode, at least) — that would defeat the purpose.
- NOTES
- 22 2 The above requirements imply that an implementation conforming to this Standard may support some of the capabilities required by a Specialized Needs Annex without supporting all required capabilities.
- 22.a **Discussion:** A conforming implementation can partially support a Specialized Needs Annex. Such an implementation does not conform to the Annex, but it does conform to the Standard.

1.1.4 Method of Description and Syntax Notation

- 1 The form of an Ada program is described by means of a context-free syntax together with context-dependent requirements expressed by narrative rules.
- 2 The meaning of Ada programs is described by means of narrative rules defining both the effects of each construct and the composition rules for constructs.

The context-free syntax of the language is described using a simple variant of Backus-Naur Form. In particular:	3
<ul style="list-style-type: none"> Lower case words in a sans-serif font, some containing embedded underlines, are used to denote syntactic categories, for example: 	4
<code>case_statement</code>	5
<ul style="list-style-type: none"> Boldface words are used to denote reserved words, for example: 	6
<code>array</code>	7
<ul style="list-style-type: none"> Square brackets enclose optional items. Thus the two following rules are equivalent. 	8
<code>{AI95-00433-01} simple_return_statement ::= return [expression];</code>	9/2
<code>simple_return_statement ::= return; return expression;</code>	
<ul style="list-style-type: none"> Curly brackets enclose a repeated item. The item may appear zero or more times; the repetitions occur from left to right as with an equivalent left-recursive rule. Thus the two following rules are equivalent. 	10
<code>term ::= factor {multiplying_operator factor}</code>	11
<code>term ::= factor term multiplying_operator factor</code>	
<ul style="list-style-type: none"> A vertical line separates alternative items unless it occurs immediately after an opening curly bracket, in which case it stands for itself: 	12
<code>constraint ::= scalar_constraint composite_constraint</code>	13
<code>discrete_choice_list ::= discrete_choice { discrete_choice }</code>	
<ul style="list-style-type: none"> If the name of any syntactic category starts with an italicized part, it is equivalent to the category name without the italicized part. The italicized part is intended to convey some semantic information. For example <i>subtype_name</i> and <i>task_name</i> are both equivalent to <i>name</i> alone. 	14
Discussion: The grammar given in this International Standard is not LR(1). In fact, it is ambiguous; the ambiguities are resolved by the overload resolution rules (see 8.6).	14.a
We often use “if” to mean “if and only if” in definitions. For example, if we define “photogenic” by saying, “A type is photogenic if it has the following properties...,” we mean that a type is photogenic if <i>and only if</i> it has those properties. It is usually clear from the context, and adding the “and only if” seems too cumbersome.	14.b
When we say, for example, “a <i>declarative_item</i> of a <i>declarative_part</i> ”, we are talking about a <i>declarative_item</i> immediately within that <i>declarative_part</i> . When we say “a <i>declarative_item</i> in, or within, a <i>declarative_part</i> ”, we are talking about a <i>declarative_item</i> anywhere in the <i>declarative_part</i> , possibly deeply nested within other <i>declarative_parts</i> . (This notation doesn't work very well for names, since the name “of” something also has another meaning.)	14.c
When we refer to the name of a language-defined entity (for example, Duration), we mean the language-defined entity even in programs where the declaration of the language-defined entity is hidden by another declaration. For example, when we say that the expected type for the expression of a <i>delay_relative_statement</i> is Duration, we mean the language-defined type Duration that is declared in Standard, not some type Duration the user might have declared.	14.d
<code>{AI95-00285-01} {AI05-0004-1} {AI05-0262-1}</code> The delimiters, compound delimiters, reserved words, and <i>numeric_literals</i> are exclusively made of the characters whose code point is between 16#20# and 16#7E#, inclusively. The special characters for which names are defined in this International Standard (see 2.1) belong to the same range. [For example, the character E in the definition of <i>exponent</i> is the character whose name is “LATIN CAPITAL LETTER E”, not “GREEK CAPITAL LETTER EPSILON”.]	14.1/3
Discussion: This just means that programs can be written in plain ASCII characters; no characters outside of the 7-bit range are required.	14.e/2
<code>{AI95-00395-01} {AI05-0227-1} {AI05-0299-1}</code> When this International Standard mentions the conversion of some character or sequence of characters to upper case, it means the character or sequence	14.2/3

of characters obtained by using simple upper case mapping, as defined by documents referenced in the note in Clause 1 of ISO/IEC 10646:2011.

- 14.e.1/3 *This paragraph was deleted.*
- 15 A *syntactic category* is a nonterminal in the grammar defined in BNF under “Syntax.” Names of syntactic categories are set in a different font, like `this`.
- 16 A *construct* is a piece of text (explicit or implicit) that is an instance of a syntactic category defined under “Syntax”.
- 16.a **Ramification:** For example, an expression is a construct. A declaration is a construct, whereas the thing declared by a declaration is an “entity.”
- 16.b **Discussion:** “Explicit” and “implicit” don't mean exactly what you might think they mean: The text of an instance of a generic is considered explicit, even though it does not appear explicitly (in the nontechnical sense) in the program text, and even though its meaning is not defined entirely in terms of that text.
- 17 A *constituent* of a construct is the construct itself, or any construct appearing within it.
- 18 Whenever the run-time semantics defines certain actions to happen in an *arbitrary order*, this means that the implementation shall arrange for these actions to occur in a way that is equivalent to some sequential order, following the rules that result from that sequential order. When evaluations are defined to happen in an arbitrary order, with conversion of the results to some subtypes, or with some run-time checks, the evaluations, conversions, and checks may be arbitrarily interspersed, so long as each expression is evaluated before converting or checking its value. [Note that the effect of a program can depend on the order chosen by the implementation. This can happen, for example, if two actual parameters of a given call have side effects.]
- 18.a **Discussion:** Programs will be more portable if their external effect does not depend on the particular order chosen by an implementation.
- 18.b **Ramification:** Additional reordering permissions are given in 11.6, “Exceptions and Optimization”.
- 18.c There is no requirement that the implementation always choose the same order in a given kind of situation. In fact, the implementation is allowed to choose a different order for two different executions of the same construct. However, we expect most implementations will behave in a relatively predictable manner in most situations.
- 18.d **Reason:** The “sequential order” wording is intended to allow the programmer to rely on “benign” side effects. For example, if F is a function that returns a unique integer by incrementing some global and returning the result, a call such as P(F, F) is OK if the programmer cares only that the two results of F are unique; the two calls of F cannot be executed in parallel, unless the compiler can prove that parallel execution is equivalent to some sequential order.

NOTES

- 19 3 The syntax rules describing structured constructs are presented in a form that corresponds to the recommended paragraphing. For example, an `if_statement` is defined as:
- 20 `if_statement ::=`
`if condition then`
`sequence_of_statements`
`{elsif condition then`
`sequence_of_statements}`
`[else`
`sequence_of_statements]`
`end if;`
- 21 4 The line breaks and indentation in the syntax rules indicate the recommended line breaks and indentation in the corresponding constructs. The preferred places for other line breaks are after semicolons.

Wording Changes from Ada 95

- 21.a/2 {A195-00285-01} We now explicitly say that the lexical elements of the language (with a few exceptions) are made up of characters in the lower half of the Latin-1 character set. This is needed to avoid confusion given the new capability to use most ISO 10646 characters in identifiers and strings.
- 21.b/2 {A195-00395-01} We now explicitly define what the Standard means by upper case, as there are many possibilities for ISO 10646 characters.

{AI95-00433-01} The example for square brackets has been changed as there is no longer a `return_statement` syntax rule. 21.c/2

Wording Changes from Ada 2005

{AI05-0227-1} **Correction:** Upper case is defined by "simple upper case mapping", because "full case folding" is a mapping (mostly) to lower case. 21.d/3

1.1.5 Classification of Errors

Implementation Requirements

The language definition classifies errors into several different categories: 1

- Errors that are required to be detected prior to run time by every Ada implementation; 2

These errors correspond to any violation of a rule given in this International Standard, other than those listed below. In particular, violation of any rule that uses the terms shall, allowed, permitted, legal, or illegal belongs to this category. Any program that contains such an error is not a legal Ada program; on the other hand, the fact that a program is legal does not mean, *per se*, that the program is free from other forms of error. 3

The rules are further classified as either compile time rules, or post compilation rules, depending on whether a violation has to be detected at the time a compilation unit is submitted to the compiler, or may be postponed until the time a compilation unit is incorporated into a partition of a program. 4

Ramification: See, for example, 10.1.3, “Subunits of Compilation Units”, for some errors that are detected only after compilation. Implementations are allowed, but not required, to detect post compilation rules at compile time when possible. 4.a

- Errors that are required to be detected at run time by the execution of an Ada program; 5

The corresponding error situations are associated with the names of the predefined exceptions. Every Ada compiler is required to generate code that raises the corresponding exception if such an error situation arises during program execution. [If such an error situation is certain to arise in every execution of a construct, then an implementation is allowed (although not required) to report this fact at compilation time.] 6

- Bounded errors; 7

The language rules define certain kinds of errors that need not be detected either prior to or during run time, but if not detected, the range of possible effects shall be bounded. The errors of this category are called *bounded errors*. The possible effects of a given bounded error are specified for each such error, but in any case one possible effect of a bounded error is the raising of the exception `Program_Error`. 8

- Erroneous execution. 9

In addition to bounded errors, the language rules define certain kinds of errors as leading to *erroneous execution*. Like bounded errors, the implementation need not detect such errors either prior to or during run time. Unlike bounded errors, there is no language-specified bound on the possible effect of erroneous execution; the effect is in general not predictable. 10

Ramification: Executions are erroneous, not programs or parts of programs. Once something erroneous happens, the execution of the entire program is erroneous from that point on, and potentially before given possible reorderings permitted by 11.6 and elsewhere. We cannot limit it to just one partition, since partitions are not required to live in separate address spaces. (But implementations are encouraged to limit it as much as possible.) 10.a

Suppose a program contains a pair of things that will be executed “in an arbitrary order.” It is possible that one order will result in something sensible, whereas the other order will result in erroneous execution. If the implementation happens to choose the first order, then the execution is not erroneous. This may seem odd, but it is not harmful. 10.b

- 10.c Saying that something is erroneous is semantically equivalent to saying that the behavior is unspecified. However, “erroneous” has a slightly more disapproving flavor.

Implementation Permissions

- 11 [An implementation may provide *nonstandard modes* of operation. Typically these modes would be selected by a `pragma` or by a command line switch when the compiler is invoked. When operating in a nonstandard mode, the implementation may reject `compilation_units` that do not conform to additional requirements associated with the mode, such as an excessive number of warnings or violation of coding style guidelines. Similarly, in a nonstandard mode, the implementation may apply special optimizations or alternative algorithms that are only meaningful for programs that satisfy certain criteria specified by the implementation. In any case, an implementation shall support a *standard* mode that conforms to the requirements of this International Standard; in particular, in the standard mode, all legal `compilation_units` shall be accepted.]

- 11.a **Discussion:** These permissions are designed to authorize explicitly the support for alternative modes. Of course, nothing we say can prevent them anyway, but this (redundant) paragraph is designed to indicate that such alternative modes are in some sense “approved” and even encouraged where they serve the specialized needs of a given user community, so long as the standard mode, designed to foster maximum portability, is always available.

Implementation Advice

- 12 If an implementation detects a bounded error or erroneous execution, it should raise `Program_Error`.
- 12.a.1/2 **Implementation Advice:** If a bounded error or erroneous execution is detected, `Program_Error` should be raised.

Wording Changes from Ada 83

- 12.a Some situations that are erroneous in Ada 83 are no longer errors at all. For example, depending on the parameter passing mechanism when unspecified is possibly nonportable, but not erroneous.
- 12.b Other situations that are erroneous in Ada 83 are changed to be bounded errors. In particular, evaluating an uninitialized scalar variable is a bounded error. The possible results are to raise `Program_Error` (as always), or to produce a machine-representable value (which might not be in the subtype of the variable). Violating a `Range_Check` or `Overflow_Check` raises `Constraint_Error`, even if the value came from an uninitialized variable. This means that optimizers can no longer “assume” that all variables are initialized within their subtype's range. Violating a check that is suppressed remains erroneous.
- 12.c The “incorrect order dependences” category of errors is removed. All such situations are simply considered potential nonportabilities. This category was removed due to the difficulty of defining what it means for two executions to have a “different effect.” For example, if a function with a side effect is called twice in a single expression, it is not in principle possible for the compiler to decide whether the correctness of the resulting program depends on the order of execution of the two function calls. A compile time warning might be appropriate, but raising of `Program_Error` at run time would not be.

1.2 Normative References

- 1/3 {*AI05-0299-1*} The following documents, in whole or in part, are normatively referenced in this document and are indispensable for its application. For dated references, only the edition cited applies. For undated references, the latest edition of the referenced document (including any amendments) applies.
- 1.1/3 {*AI05-0127-2*} {*AI05-0299-1*} ISO 639-3:2007, *Codes for the representation of names of languages — Part 3: Alpha-3 code for comprehensive coverage of languages*.

1.3 Terms and Definitions

{AI95-00415-01} Terms are defined throughout this International Standard, indicated by <i>italic</i> type. Terms explicitly defined in this International Standard are not to be presumed to refer implicitly to similar terms defined elsewhere. Mathematical terms not defined in this International Standard are to be interpreted according to the <i>CRC Concise Encyclopedia of Mathematics, Second Edition</i> . Other terms not defined in this International Standard are to be interpreted according to the <i>Webster's Third New International Dictionary of the English Language</i> . Informal descriptions of some terms are also given in Annex N, “Glossary”.	1/2
Discussion: The index contains an entry for every defined term.	1.a
{AI95-00415-01} The contents of the <i>CRC Concise Encyclopedia of Mathematics, Second Edition</i> can be accessed on http://www.mathworld.com . The ISBN number of the book is ISBN 1584883472.	1.a.1/2
Glossary entry: Each term defined in Annex N is marked like this.	1.b
Discussion: Here are some AARM-only definitions: The Ada Rapporteur Group (ARG) interprets the Ada Reference Manual. An Ada Issue (AI) is a numbered ruling from the ARG. Ada Issues created for Ada 83 are denoted as "AI83", while Ada Issues created for Ada 95 are denoted as "AI95" in this document. Similarly, Ada Issues created for Ada 2005 are denoted as "AI05" The Ada Commentary Integration Document (ACID) is an edition of the Ada 83 RM in which clearly marked insertions and deletions indicate the effect of integrating the approved AIs. The Uniformity Rapporteur Group (URG) issued recommendations intended to increase uniformity across Ada implementations. The functions of the URG have been assumed by the ARG. A Uniformity Issue (UI) was a numbered recommendation from	1.c/3

the URG. A Defect Report and Response is an official query to WG9 about an error in the standard. Defect Reports are processed by the ARG, and are referenced here by their ISO numbers: 8652/nnnn. Most changes to the Ada 95 standard include reference(s) to the Defect Report(s) that prompted the change. The *Ada Conformity Assessment Test Suite (ACATS)* is a set of tests intended to check the conformity of Ada implementations to this standard. This set of tests was previously known as the Ada Compiler Validation Capability (ACVC).

2 Lexical Elements

{AI05-0299-1} [The text of a program consists of the texts of one or more compilations. The text of a compilation is a sequence of lexical elements, each composed of characters; the rules of composition are given in this clause. Pragmas, which provide certain information for the compiler, are also described in this clause.] 1/3

2.1 Character Set

{AI95-00285-01} {AI95-00395-01} {AI05-0266-1} The character repertoire for the text of an Ada program consists of the entire coding space described by the ISO/IEC 10646:2011 Universal Multiple-Octet Coded Character Set. This coding space is organized in *planes*, each plane comprising 65536 characters. 1/3

This paragraph was deleted. {AI95-00285-01} 1.a/2

This paragraph was deleted. {AI95-00285-01} 1.b/2

Discussion: {AI95-00285-01} {AI05-0266-1} It is our intent to follow the terminology of ISO/IEC 10646:2011 where appropriate, and to remain compatible with the character classifications defined in A.3, “Character Handling”. 1.c/3

Syntax

Paragraphs 2 and 3 were deleted.

{AI95-00285-01} {AI95-00395-01} {AI05-0266-1} A character is defined by this International Standard for each cell in the coding space described by ISO/IEC 10646:2011, regardless of whether or not ISO/IEC 10646:2011 allocates a character to that cell. 3.1/3

Static Semantics

{AI95-00285-01} {AI95-00395-01} {AI05-0079-1} {AI05-0262-1} {AI05-0266-1} The coded representation for characters is implementation defined [(it need not be a representation defined within ISO/IEC 10646:2011)]. A character whose relative code point in its plane is 16#FFFE# or 16#FFFF# is not allowed anywhere in the text of a program. The only characters allowed outside of comments are those in categories `other_format`, `format_effector`, and `graphic_character`. 4/3

Implementation defined: The coded representation for the text of an Ada program. 4.a

Ramification: {AI95-00285-01} Note that this rule doesn't really have much force, since the implementation can represent characters in the source in any way it sees fit. For example, an implementation could simply define that what seems to be an `other_private_use` character is actually a representation of the space character. 4.b/2

{AI95-00285-01} {AI05-0266-1} {AI05-0299-1} The semantics of an Ada program whose text is not in Normalization Form KC (as defined by Clause 21 of ISO/IEC 10646:2011) is implementation defined. 4.1/3

Implementation defined: The semantics of an Ada program whose text is not in Normalization Form KC. 4.c/2

{AI95-00285-01} {AI05-0266-1} {AI05-0299-1} The description of the language definition in this International Standard uses the character properties General Category, Simple Uppercase Mapping, Uppercase Mapping, and Special Case Condition of the documents referenced by the note in Clause 1 of ISO/IEC 10646:2011. The actual set of graphic symbols used by an implementation for the visual representation of the text of an Ada program is not specified. 5/3

{AI95-00285-01} {AI05-0266-1} Characters are categorized as follows: 6/3

Discussion: {AI05-0005-1} {AI05-0262-1} {AI05-0266-1} Our character classification considers that the cells not allocated in ISO/IEC 10646:2011 are graphic characters, except for those whose relative code point in their plane is 16#FFFE# or 16#FFFF#. This seems to provide the best compatibility with future versions of ISO/IEC 10646, as future characters can already be used in Ada character and string literals. 6.a/3

This paragraph was deleted. {AI95-00285-01} 7/2

- 8/2 {AI95-00285-01} letter_uppercase
Any character whose General Category is defined to be “Letter, Uppercase”.
- 9/2 {AI95-00285-01} letter_lowercase
Any character whose General Category is defined to be “Letter, Lowercase”.
- 9.a/1 *This paragraph was deleted. {8652/0001} {AI95-00124-01}*
- 9.1/2 {AI95-00285-01} letter_titlecase
Any character whose General Category is defined to be “Letter, Titlecase”.
- 9.2/2 {AI95-00285-01} letter_modifier
Any character whose General Category is defined to be “Letter, Modifier”.
- 9.3/2 {AI95-00285-01} letter_other
Any character whose General Category is defined to be “Letter, Other”.
- 9.4/2 {AI95-00285-01} mark_non_spacing
Any character whose General Category is defined to be “Mark, Non-Spacing”.
- 9.5/2 {AI95-00285-01} mark_spacing_combining
Any character whose General Category is defined to be “Mark, Spacing Combining”.
- 10/2 {AI95-00285-01} number_decimal
Any character whose General Category is defined to be “Number, Decimal”.
- 10.1/2 {AI95-00285-01} number_letter
Any character whose General Category is defined to be “Number, Letter”.
- 10.2/2 {AI95-00285-01} punctuation_connector
Any character whose General Category is defined to be “Punctuation, Connector”.
- 10.3/2 {AI95-00285-01} other_format
Any character whose General Category is defined to be “Other, Format”.
- 11/2 {AI95-00285-01} separator_space
Any character whose General Category is defined to be “Separator, Space”.
- 12/2 {AI95-00285-01} separator_line
Any character whose General Category is defined to be “Separator, Line”.
- 12.1/2 {AI95-00285-01} separator_paragraph
Any character whose General Category is defined to be “Separator, Paragraph”.
- 13/3 {AI95-00285-01} {AI05-0262-1} format_effector
The characters whose code points are 16#09# (CHARACTER TABULATION), 16#0A# (LINE FEED), 16#0B# (LINE TABULATION), 16#0C# (FORM FEED), 16#0D# (CARRIAGE RETURN), 16#85# (NEXT LINE), and the characters in categories separator_line and separator_paragraph.
- 13.a/2 **Discussion:** ISO/IEC 10646:2003 does not define the names of control characters, but rather refers to the names defined by ISO/IEC 6429:1992. These are the names that we use here.
- 13.1/2 {AI95-00285-01} other_control
Any character whose General Category is defined to be “Other, Control”, and which is not defined to be a format_effector.
- 13.2/2 {AI95-00285-01} other_private_use
Any character whose General Category is defined to be “Other, Private Use”.
- 13.3/2 {AI95-00285-01} other_surrogate
Any character whose General Category is defined to be “Other, Surrogate”.

{AI95-00285-01} *{AI95-00395-01}* *{AI05-0262-1}* `graphic_character` 14/3
 Any character that is not in the categories `other_control`, `other_private_use`, `other_surrogate`, `format_effector`, and whose relative code point in its plane is neither `16#FFFE#` nor `16#FFFF#`.

This paragraph was deleted. 14.a/2

Discussion: *{AI95-00285-01}* We considered basing the definition of lexical elements on Annex A of ISO/IEC TR 10176 (4th edition), which lists the characters which should be supported in identifiers for all programming languages, but we finally decided against this option. Note that it is not our intent to diverge from ISO/IEC TR 10176, except to the extent that ISO/IEC TR 10176 itself diverges from ISO/IEC 10646:2003 (which is the case at the time of this writing [January 2005]). 14.b/2

More precisely, we intend to align strictly with ISO/IEC 10646:2003. It must be noted that ISO/IEC TR 10176 is a Technical Report while ISO/IEC 10646:2003 is a Standard. If one has to make a choice, one should conform with the Standard rather than with the Technical Report. And, it turns out that one *must* make a choice because there are important differences between the two: 14.c/2

- ISO/IEC TR 10176 is still based on ISO/IEC 10646:2000 while ISO/IEC 10646:2003 has already been published for a year. We cannot afford to delay the adoption of our amendment until ISO/IEC TR 10176 has been revised. 14.d/2
- There are considerable differences between the two editions of ISO/IEC 10646, notably in supporting characters beyond the BMP (this might be significant for some languages, e.g. Korean). 14.e/2
- ISO/IEC TR 10176 does not define case conversion tables, which are essential for a case-insensitive language like Ada. To get case conversion tables, we would have to reference either ISO/IEC 10646:2003 or Unicode, or we would have to invent our own. 14.f/2

For the purpose of defining the lexical elements of the language, we need character properties like categorization, as well as case conversion tables. These are mentioned in ISO/IEC 10646:2003 as useful for implementations, with a reference to Unicode. Machine-readable tables are available on the web at URLs: 14.g/2

<http://www.unicode.org/Public/4.0-Update/UnicodeData-4.0.0.txt> 14.h/2
<http://www.unicode.org/Public/4.0-Update/CaseFolding-4.0.0.txt>

with an explanatory document found at URL: 14.i/2

<http://www.unicode.org/Public/4.0-Update/UCD-4.0.0.html> 14.j/2

The actual text of the standard only makes specific references to the corresponding clauses of ISO/IEC 10646:2003, not to Unicode. 14.k/2

{AI95-00285-01} *{AI05-0266-1}* The following names are used when referring to certain characters (the first name is that given in ISO/IEC 10646:2011): 15/3

Discussion: *{AI95-00285-01}* *{AI05-0266-1}* This table serves to show the correspondence between ISO/IEC 10646:2011 names and the graphic symbols (glyphs) used in this International Standard. These are the characters that play a special role in the syntax of Ada. 15.a/3

graphic symbol	name	graphic symbol	name
"	quotation mark	:	colon
#	number sign	;	semicolon
&	ampersand	<	less-than sign
'	apostrophe, tick	=	equals sign
(left parenthesis	>	greater-than sign
)	right parenthesis	_	low line, underline
*	asterisk, multiply		vertical line
+	plus sign	/	solidus, divide
,	comma	!	exclamation point
-	hyphen-minus, minus	%	percent sign
.	full stop, dot, point		

Implementation Requirements

{AI05-0286-1} An Ada implementation shall accept Ada source code in UTF-8 encoding, with or without a BOM (see A.4.11), where every character is represented by its code point. The character pair 16/3

CARRIAGE RETURN/LINE FEED (code points 16#0D# 16#0A#) signifies a single end of line (see 2.2); every other occurrence of a `format_effector` other than the character whose code point position is 16#09# (CHARACTER TABULATION) also signifies a single end of line.

- 16.a/3 **Reason:** {AI05-0079-1} {AI05-0286-1} This is simply requiring that an Ada implementation be able to directly process the ACATS, which is provided in the described format. Note that files that only contain characters with code points in the first 128 (which is the majority of the ACATS) are represented in the same way in both UTF-8 and in "plain" string format. The ACATS includes a BOM in files that have any characters with code points greater than 127. Note that the BOM contains characters not legal in Ada source code, so an implementation can use that to automatically distinguish between files formatted as plain Latin-1 strings and UTF-8 with BOM.
- 16.b/3 We allow line endings to be both represented as the pair CR LF (as in Windows and the ACATS), and as single `format_effector` characters (usually LF, as in Linux), in order that files created by standard tools on most operating systems will meet the standard format. We specify how many line endings each represent so that compilers use the same line numbering for standard source files.
- 16.c/3 This requirement increases portability by having a format that is accepted by all Ada compilers. Note that implementations can support other source representations, including structured representations like a parse tree.

Implementation Permissions

- 17/3 {AI95-00285-01} {AI05-0266-1} The categories defined above, as well as case mapping and folding, may be based on an implementation-defined version of ISO/IEC 10646 (2003 edition or later).
- 17.b/3 **Ramification:** The exact categories, case mapping, and case folding chosen affects identifiers, the result of `'[[Wide_]Wide_]Image`, and packages `Wide_Characters.Handling` and `Wide_Wide_Characters.Handling`.
- 17.c/3 **Discussion:** This permission allows implementations to upgrade to using a newer character set standard whenever that makes sense, rather than having to wait for the next Ada Standard. But the character set standard used cannot be older than ISO/IEC 10646:2003 (which is essentially similar to Unicode 4.0).

NOTES

- 18/2 1 {AI95-00285-01} The characters in categories `other_control`, `other_private_use`, and `other_surrogate` are only allowed in comments.
- 19.a/3 *This paragraph was deleted.* {AI05-0286-1}

Extensions to Ada 83

- 19.b Ada 95 allows 8-bit and 16-bit characters, as well as implementation-specified character sets.

Wording Changes from Ada 83

- 19.c/3 {AI95-00285-01} {AI05-0299-1} The syntax rules in this subclause are modified to remove the emphasis on basic characters vs. others. (In this day and age, there is no need to point out that you can write programs without using (for example) lower case letters.) In particular, `character` (representing all characters usable outside comments) is added, and `basic_graphic_character`, `other_special_character`, and `basic_character` are removed. `Special_character` is expanded to include Ada 83's `other_special_character`, as well as new 8-bit characters not present in Ada 83. Ada 2005 removes `special_character` altogether; we want to stick to ISO/IEC 10646:2003 character classifications. Note that the term "basic letter" is used in A.3, "Character Handling" to refer to letters without diacritical marks.
- 19.d/2 {AI95-00285-01} Character names now come from ISO/IEC 10646:2003.
- 19.e/2 *This paragraph was deleted.* {AI95-00285-01}

Extensions to Ada 95

- 19.f/2 {AI95-00285-01} {AI95-00395-01} Program text can use most characters defined by ISO-10646:2003. This subclause has been rewritten to use the categories defined in that Standard. This should ease programming in languages other than English.

Inconsistencies With Ada 2005

- 19.g/3 {AI05-0299-1} {AI05-0266-1} An implementation is allowed (but not required) to use a newer character set standard to determine the categories, case mapping, and case folding. Doing so will change the results of attributes `'[[Wide_]Wide_]Image` and the packages `[Wide_]Wide_Characters.Handling` in the case of a few rarely used characters. (This also could make some identifiers illegal, for characters that are no longer classified as letters.) This is unlikely to be a problem in practice. Moreover, truly portable Ada 2012 programs should avoid using in these contexts

any characters that would have different classifications in any character set standards issued since 10646:2003 (since the compiler can use any such standard as the basis for its classifications).

Wording Changes from Ada 2005

{AI05-0079-1} **Correction:** Clarified that only characters in the categories defined here are allowed in the source of an Ada program. This was clear in Ada 95, but Amendment 1 dropped the wording instead of correcting it. 19.h/3

{AI05-0286-1} A standard source representation is defined that all compilers are expected to process. Since this is the same format as the ACATS, it seems unlikely that there are any implementations that don't meet this requirement. Moreover, other representations are still permitted, and the "impossible or impractical" loophole (see 1.1.3) can be invoked for any implementations that cannot directly process the ACATS. 19.i/3

2.2 Lexical Elements, Separators, and Delimiters

Static Semantics

The text of a program consists of the texts of one or more compilations. The text of each compilation is a sequence of separate *lexical elements*. Each lexical element is formed from a sequence of characters, and is either a delimiter, an identifier, a reserved word, a `numeric_literal`, a `character_literal`, a `string_literal`, or a comment. The meaning of a program depends only on the particular sequences of lexical elements that form its compilations, excluding comments. 1

{AI95-00285-01} {AI05-0262-1} The text of a compilation is divided into *lines*. In general, the representation for an end of line is implementation defined. However, a sequence of one or more `format_effectors` other than the character whose code point is 16#09# (CHARACTER TABULATION) signifies at least one end of line. 2/3

Implementation defined: The representation for an end of line. 2.a

{AI95-00285-01} [In some cases an explicit *separator* is required to separate adjacent lexical elements.] A separator is any of a `separator_space`, a `format_effector`, or the end of a line, as follows: 3/2

- {AI95-00285-01} A `separator_space` is a separator except within a comment, a `string_literal`, or a `character_literal`. 4/2
- {AI95-00285-01} {AI05-0262-1} The character whose code point is 16#09# (CHARACTER TABULATION) is a separator except within a comment. 5/3
- The end of a line is always a separator. 6

One or more separators are allowed between any two adjacent lexical elements, before the first of each compilation, or after the last. At least one separator is required between an identifier, a reserved word, or a `numeric_literal` and an adjacent identifier, reserved word, or `numeric_literal`. 7

{AI05-0079-1} One or more `other_format` characters are allowed anywhere that a separator is[; any such characters have no effect on the meaning of an Ada program]. 7.1/3

{AI95-00285-01} A *delimiter* is either one of the following characters: 8/2

& ' () * + , - . / : ; < = > | 9

or one of the following *compound delimiters* each composed of two adjacent special characters 10

=> .. ** := /= >= <= << >> <> 11

Each of the special characters listed for single character delimiters is a single delimiter except if this character is used as a character of a compound delimiter, or as a character of a comment, `string_literal`, `character_literal`, or `numeric_literal`. 12

The following names are used when referring to compound delimiters: 13

delimiter	name
=>	arrow
..	double dot
**	double star, exponentiate
:=	assignment (pronounced: “becomes”)
/=	inequality (pronounced: “not equal”)
>=	greater than or equal
<=	less than or equal
<<	left label bracket
>>	right label bracket
<>	box

Implementation Requirements

14 An implementation shall support lines of at least 200 characters in length, not counting any characters used to signify the end of a line. An implementation shall support lexical elements of at least 200 characters in length. The maximum supported line length and lexical element length are implementation defined.

14.a **Implementation defined:** Maximum supported line length and lexical element length.

14.b **Discussion:** From URG recommendation.

Wording Changes from Ada 95

14.c/3 {AI95-00285-01} {AI05-0299-1} The wording was updated to use the new character categories defined in the preceding subclause.

Extensions to Ada 2005

14.d/3 {AI05-0079-1} **Correction:** Clarified that `other_format` characters are allowed anywhere that separators are allowed. This was intended in Ada 2005, but didn't actually make it into the wording.

2.3 Identifiers

1 Identifiers are used as names.

Syntax

2/2 {AI95-00285-01} {AI95-00395-01} `identifier ::=`
`identifier_start {identifier_start | identifier_extend}`

3/2 {AI95-00285-01} {AI95-00395-01} `identifier_start ::=`
`letter_uppercase`
`| letter_lowercase`
`| letter_titlecase`
`| letter_modifier`
`| letter_other`
`| number_letter`

- {AI95-00285-01} {AI95-00395-01} {AI05-0091-1} identifier_extend ::= 3.1/3
 mark_non_spacing
 | mark_spacing_combining
 | number_decimal
 | punctuation_connector
- {AI95-00395-01} {AI05-0091-1} An identifier shall not contain two consecutive characters in 4/3
 category punctuation_connector, or end with a character in that category.
- Reason:** This rule was stated in the syntax in Ada 95, but that has gotten too complex in Ada 2005. 4.a/3

Static Semantics

- {AI95-00285-01} {AI05-0091-1} {AI05-0227-1} {AI05-0266-1} {AI05-0299-1} Two identifiers are 5/3
 considered the same if they consist of the same sequence of characters after applying locale-independent
 simple case folding, as defined by documents referenced in the note in Clause 1 of ISO/IEC 10646:2011.
- Discussion:** {AI05-0227-1} Simple case folding is a mapping to lower case, so this is matching the defining (lower 5.a/3
 case) version of a reserved word. We could have mentioned case folding of the reserved words, but as that is an
 identity function, it would have no effect.
- {AI05-0227-1} The “documents referenced” means Unicode. Note that simple case folding is supposed to be 5.a.1/3
 compatible between Unicode versions, so the Unicode version used doesn't matter.
- {AI95-00395-01} {AI05-0091-1} {AI05-0227-1} After applying simple case folding, an identifier shall 5.3/3
 not be identical to a reserved word.
- Implementation Note:** We match the reserved words after applying case folding so that the rules for identifiers and 5.b/3
 reserved words are the same. Since a compiler usually will lexically process identifiers and reserved words the same
 way (often with the same code), this will prevent a lot of headaches.
- Ramification:** {AI05-0227-1} The rules for reserved words differ in one way: they define case conversion on letters 5.c/3
 rather than sequences. This means that it is possible that there exist some unusual sequences that are neither identifiers
 nor reserved words. We are not aware of any such sequences so long as we use simple case folding (as opposed to full
 case folding), but we have defined the rules in case any are introduced in future character set standards. This originally
 was a problem when converting to upper case: “if” and “acceß” have upper case conversions of “IF” and “ACCESS”
 respectively. We would not want these to be treated as reserved words. But neither of these cases exist when using
 simple case folding.

Implementation Permissions

- In a nonstandard mode, an implementation may support other upper/lower case equivalence rules for 6
 identifiers[, to accommodate local conventions].
- Discussion:** {AI95-00285-01} {AI05-0227-1} For instance, in most languages, the simple case folded equivalent of 6.a/3
 LATIN CAPITAL LETTER I (an upper case letter without a dot above) is LATIN SMALL LETTER I (a lower case
 letter with a dot above). In Turkish, though, LATIN CAPITAL LETTER I and LATIN CAPITAL LETTER I WITH
 DOT ABOVE are two distinct letters, so the case folded equivalent of LATIN CAPITAL LETTER I is LATIN
 SMALL LETTER DOTLESS I, and the case folded equivalent of LATIN CAPITAL LETTER I WITH DOT ABOVE
 is LATIN SMALL LETTER I. Take for instance the following identifier (which is the name of a city on the Tigris
 river in Eastern Anatolia):
- DİYARBAKIR -- *The first i is dotted, the second isn't.* 6.b/3
- A Turkish reader would expect that the above identifier is equivalent to: 6.c/3
- diyrbakır 6.d/3
- However, locale-independent simple case folding (and thus Ada) maps this to: 6.d.1/3
- diyrbakir 6.d.2/3
- which is different from any of the following identifiers: 6.e/3
- diyrbakir 6.f/2
 diyrbakır
 diyrbakir
 diyrbakır
- including the “correct” matching identifier for Turkish. Upper case conversion (used in '[Wide_]Wide_Image') 6.f.1/3
 introduces additional problems.

6.g/3 An implementation targeting the Turkish market is allowed (in fact, expected) to provide a nonstandard mode where case folding is appropriate for Turkish.

6.j/2 Lithuanian and Azeri are two other languages that present similar idiosyncrasies.

NOTES

6.1/2 2 {AI95-00285-01} Identifiers differing only in the use of corresponding upper and lower case letters are considered the same.

*Examples*7 *Examples of identifiers:*

8/2 {AI95-00433-01} Count X Get_Symbol Ethelyn Marion
 Snobol_4 X1 Page_Count Store_Next_Item
 Πλάτων -- *Plato*
 Чайковский -- *Tchaikovsky*
 Θ φ -- *Angles*

Wording Changes from Ada 83

8.a We no longer include reserved words as **identifiers**. This is not a language change. In Ada 83, **identifier** included reserved words. However, this complicated several other rules (for example, regarding implementation-defined attributes and pragmas, etc.). We now explicitly allow certain reserved words for attribute designators, to make up for the loss.

8.b **Ramification:** Because syntax rules are relevant to overload resolution, it means that if it looks like a reserved word, it is not an **identifier**. As a side effect, implementations cannot use reserved words as implementation-defined attributes or pragma names.

Extensions to Ada 95

8.c/2 {AI95-00285-01} An **identifier** can use any letter defined by ISO-10646:2003, along with several other categories. This should ease programming in languages other than English.

Incompatibilities With Ada 2005

8.d/3 {AI05-0091-1} **Correction:** `other_format` characters were removed from identifiers as the Unicode recommendations have changed. This change can only affect programs written for the original Ada 2005, so there should be few such programs.

8.e/3 {AI05-0227-1} **Correction:** We now specify simple case folding rather than full case folding. That potentially could change identifier equivalence, although it is more likely that identifiers that are considered the same in original Ada 2005 will now be considered different. This change was made because the original Ada 2005 definition was incompatible (and even inconsistent in unusual cases) with the Ada 95 identifier equivalence rules. As such, the Ada 2005 rules were rarely fully implemented, and in any case, only Ada 2005 identifiers containing wide characters could be affected.

2.4 Numeric Literals

1 There are two kinds of `numeric_literals`, *real literals* and *integer literals*. A real literal is a `numeric_literal` that includes a point; an integer literal is a `numeric_literal` without a point.

Syntax

2 `numeric_literal ::= decimal_literal | based_literal`

NOTES

3 The type of an integer literal is *universal_integer*. The type of a real literal is *universal_real*.

2.4.1 Decimal Literals

1 A `decimal_literal` is a `numeric_literal` in the conventional decimal notation (that is, the base is ten).

Syntax

2 `decimal_literal ::= numeral [.numeral] [exponent]`

numeral ::= digit {[underline] digit} 3
 exponent ::= E [+] numeral | E – numeral 4
 {AI95-00285-01} digit ::= 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 4.1/2
 An exponent for an integer literal shall not have a minus sign. 5
Ramification: Although this rule is in this subclause, it applies also to the next subclause. 5.a

Static Semantics

An underline character in a numeric_literal does not affect its meaning. The letter E of an exponent can be written either in lower case or in upper case, with the same meaning. 6

Ramification: Although these rules are in this subclause, they apply also to the next subclause. 6.a

An exponent indicates the power of ten by which the value of the decimal_literal without the exponent is to be multiplied to obtain the value of the decimal_literal with the exponent. 7

Examples

Examples of decimal literals: 8

12 0 1E6 123_456 -- integer literals 9
 12.0 0.0 0.456 3.14159_26 -- real literals

Wording Changes from Ada 83

We have changed the syntactic category name integer to be numeral. We got this idea from ACID. It avoids the confusion between this and integers. (Other places don't offer similar confusions. For example, a string_literal is different from a string.) 9.a

2.4.2 Based Literals

[A based_literal is a numeric_literal expressed in a form that specifies the base explicitly.] 1

Syntax

based_literal ::= 2
 base # based_numeral [.based_numeral] # [exponent]
 base ::= numeral 3
 based_numeral ::= 4
 extended_digit {[underline] extended_digit}
 extended_digit ::= digit | A | B | C | D | E | F 5

Legality Rules

The *base* (the numeric value of the decimal numeral preceding the first #) shall be at least two and at most sixteen. The extended_digits A through F represent the digits ten through fifteen, respectively. The value of each extended_digit of a based_literal shall be less than the base. 6

Static Semantics

The conventional meaning of based notation is assumed. An exponent indicates the power of the base by which the value of the based_literal without the exponent is to be multiplied to obtain the value of the based_literal with the exponent. The base and the exponent, if any, are in decimal notation. 7

The extended_digits A through F can be written either in lower case or in upper case, with the same meaning. 8

Examples

9 *Examples of based literals:*

10 2#1111_1111# 16#FF# 016#0ff# -- integer literals of value 255
 16#E#E1 2#1110_0000# -- integer literals of value 224
 16#F.FF#E+2 2#1.1111_1111_1110#E11 -- real literals of value 4095.0

Wording Changes from Ada 83

10.a The rule about which letters are allowed is now encoded in BNF, as suggested by Mike Woodger. This is clearly more readable.

2.5 Character Literals

1 [A `character_literal` is formed by enclosing a graphic character between two apostrophe characters.]

Syntax

2 `character_literal ::= 'graphic_character'`

NOTES

3 4 A `character_literal` is an enumeration literal of a character type. See 3.5.2.

Examples

4 *Examples of character literals:*

5/2 {AI95-00433-01} 'A' '*' ' ' ' ' ' '
 'L' 'I' 'Λ' -- Various els.
 '∞' 'ℵ' -- Big numbers - infinity and aleph.

Wording Changes from Ada 83

5.a/3 {AI05-0299-1} The definitions of the values of literals are in Clauses 3 and 4, rather than here, since it requires knowledge of types.

2.6 String Literals

1 [A `string_literal` is formed by a sequence of graphic characters (possibly none) enclosed between two quotation marks used as string brackets. They are used to represent `operator_symbols` (see 6.1), values of a string type (see 4.2), and array subaggregates (see 4.3.3).]

Syntax

2 `string_literal ::= "{string_element}"`

3 `string_element ::= "" | non_quotation_mark_graphic_character`

4 A `string_element` is either a pair of quotation marks (""), or a single `graphic_character` other than a quotation mark.

Static Semantics

5 The *sequence of characters* of a `string_literal` is formed from the sequence of `string_elements` between the bracketing quotation marks, in the given order, with a `string_element` that is "" becoming a single quotation mark in the sequence of characters, and any other `string_element` being reproduced in the sequence.

6 A *null string literal* is a `string_literal` with no `string_elements` between the quotation marks.

NOTES

7 5 An end of line cannot appear in a `string_literal`.

7.1/2 6 {AI95-00285-01} No transformation is performed on the sequence of characters of a `string_literal`.

*Examples**Examples of string literals:*

```

{AI95-00433-01} "Message of the day:" 8
" " "A" "" -- a null string literal 9/2
" " "A" "" -- three string literals of length 1

"Characters such as $, %, and } are allowed in string literals"
"Archimedes said "Εύρηκα""
"Volume of cylinder ( $\pi r^2 h$ ) = "

```

Wording Changes from Ada 83

The wording has been changed to be strictly lexical. No mention is made of string or character values, since `string_literals` are also used to represent `operator_symbols`, which don't have a defined value. 9.a

The syntax is described differently. 9.b

Wording Changes from Ada 95

{AI95-00285-01} We explicitly say that the characters of a `string_literal` should be used as is. In particular, no normalization or folding should be performed on a `string_literal`. 9.c/2

2.7 Comments

A comment starts with two adjacent hyphens and extends up to the end of the line. 1

Syntax

```
comment ::= -- {non_end_of_line_character} 2
```

A comment may appear on any line of a program. 3

Static Semantics

The presence or absence of comments has no influence on whether a program is legal or illegal. Furthermore, comments do not influence the meaning of a program; their sole purpose is the enlightenment of the human reader. 4

*Examples**Examples of comments:*

```

-- the last sentence above echoes the Algol 68 report 5
-- the last sentence above echoes the Algol 68 report 6

end; -- processing of Line is complete

-- a long comment may be split onto
-- two or more consecutive lines

----- the first two hyphens start the comment

```

2.8 Pragmas

A pragma is a compiler directive. There are language-defined pragmas that give instructions for optimization, listing control, etc. An implementation may support additional (implementation-defined) pragmas. 1

Language Design Principles

{AI05-0100-1} {AI05-0163-1} In general, if all pragmas are treated as unrecognized pragmas, the program should remain both syntactically and semantically legal. There are a few exceptions to this general principle (for example, `pragma Import` can eliminate the need for a completion), but the principle remains, and is strictly true at the syntactic 1.a/3

level. Certainly any implementation-defined pragmas should obey this principle both syntactically and semantically, so that if the pragmas are not recognized by some other implementation, the program will remain legal.

Syntax

- 2 **pragma** ::=
- pragma** identifier [(pragma_argument_association {, pragma_argument_association})];
- 3/3 {AI05-0290-1} pragma_argument_association ::=
- [pragma_argument_identifier =>] name
- | [pragma_argument_identifier =>] expression
- | pragma_argument_aspect_mark => name
- | pragma_argument_aspect_mark => expression
- 4/3 {AI05-0290-1} In a pragma, any pragma_argument_associations without a
- pragma_argument_identifier* or *pragma_argument_aspect_mark* shall precede any associations with
- a *pragma_argument_identifier* or *pragma_argument_aspect_mark*.
- 5 Pragmas are only allowed at the following places in a program:
- 6

7/3 • After a semicolon delimiter, but not within a *formal_part* or *discriminant_part*.

 • {AI05-0100-1} {AI05-0163-1} At any place where the syntax rules allow a construct defined

 by a syntactic category whose name ends with “*declaration*”, “*item*”, “*statement*”, “*clause*”,

 or “*alternative*”, or one of the syntactic categories *variant* or *exception_handler*; but not in

 place of such a construct if the construct is required, or is part of a list that is required to have

 at least one such construct.

7.1/3 • {AI05-0163-1} In place of a *statement* in a *sequence_of_statements*.

7.2/3 • {AI05-0100-1} At any place where a *compilation_unit* is allowed.

8 Additional syntax rules and placement restrictions exist for specific pragmas.

8.a **Discussion:** The above rule is written in text, rather than in BNF; the syntactic category *pragma* is not used in any

 BNF syntax rule.

8.b **Ramification:** A pragma is allowed where a *generic_formal_parameter_declaration* is allowed.

9 The *name* of a pragma is the identifier following the reserved word **pragma**. The name or expression of

 a *pragma_argument_association* is a *pragma argument*.

9.a/2 **To be honest:** {AI95-00284-02} For compatibility with Ada 83, the name of a pragma may also be “**interface**”, which

 is not an identifier (because it is a reserved word). See J.12.

10/3 {AI05-0272-1} An *identifier specific to a pragma* is an identifier or reserved word that is used in a

 pragma argument with special meaning for that pragma.

10.a **To be honest:** Whenever the syntax rules for a given pragma allow “*identifier*” as an argument of the pragma, that

identifier is an identifier specific to that pragma.

10.b/3 {AI05-0272-1} In a few cases, a reserved word is allowed as “an identifier specific to a pragma”. Even in these cases,

 the syntax still is written as *identifier* (the reserved word(s) are not shown). For example, the restriction

No_Use_Of_Attribute (see 13.12.1) allows the reserved words which can be attribute designators, but the syntax for a

 restriction does not include these reserved words.

Static Semantics

- 11 If an implementation does not recognize the name of a pragma, then it has no effect on the semantics of
- the program. Inside such a pragma, the only rules that apply are the Syntax Rules.
- 11.a **To be honest:** This rule takes precedence over any other rules that imply otherwise.
- 11.b **Ramification:** Note well: this rule applies only to pragmas whose name is not recognized. If anything else is wrong
- with a pragma (at compile time), the pragma is illegal. This is true whether the pragma is language defined or
- implementation defined.

- For example, an expression in an unrecognized **pragma** does not cause freezing, even though the rules in 13.14, “Freezing Rules” say it does; the above rule overrules those other rules. On the other hand, an expression in a recognized **pragma** causes freezing, even if this makes something illegal. 11.c
- For another example, an expression that would be ambiguous is not illegal if it is inside an unrecognized **pragma**. 11.d
- Note, however, that implementations have to recognize **pragma** `Inline(Foo)` and freeze things accordingly, even if they choose to never do inlining. 11.e
- Obviously, the contradiction needs to be resolved one way or the other. The reasons for resolving it this way are: The implementation is simple — the compiler can just ignore the **pragma** altogether. The interpretation of constructs appearing inside implementation-defined **pragmas** is implementation defined. For example: “**pragma** `Mumble(X)`;”. If the current implementation has never heard of `Mumble`, then it doesn’t know whether `X` is a name, an expression, or an identifier specific to the **pragma** `Mumble`. 11.f
- To be honest:** The syntax of individual **pragmas** overrides the general syntax for **pragma**. 11.g
- Ramification:** Thus, an identifier specific to a **pragma** is not a name, syntactically; if it were, the visibility rules would be invoked, which is not what we want. 11.h
- {AI05-0229-1} This also implies that named associations do not allow one to give the arguments in an arbitrary order — the order given in the syntax rule for each individual **pragma** must be obeyed. However, it is generally possible to leave out earlier arguments when later ones are given; for example, this is allowed by the syntax rule for **pragma** `Import` (see J.15.5, “Interfacing Pragmas”). As for subprogram calls, positional notation precedes named notation. 11.i/3
- Note that Ada 83 had no **pragmas** for which the order of named associations mattered, since there was never more than one argument that allowed named associations. 11.j
- To be honest:** The interpretation of the arguments of implementation-defined **pragmas** is implementation defined. However, the syntax rules have to be obeyed. 11.k
- Dynamic Semantics*
- Any **pragma** that appears at the place of an executable construct is executed. Unless otherwise specified for a particular **pragma**, this execution consists of the evaluation of each evaluable **pragma** argument in an arbitrary order. 12
- Ramification:** For a **pragma** that appears at the place of an elaborable construct, execution is elaboration. 12.a
- An identifier specific to a **pragma** is neither a name nor an expression — such identifiers are not evaluated (unless an implementation defines them to be evaluated in the case of an implementation-defined **pragma**). 12.b
- The “unless otherwise specified” part allows us (and implementations) to make exceptions, so a **pragma** can contain an expression that is not evaluated. Note that **pragmas** in `type_definitions` may contain expressions that depend on discriminants. 12.c
- When we wish to define a **pragma** with some run-time effect, we usually make sure that it appears in an executable context; otherwise, special rules are needed to define the run-time effect and when it happens. 12.d
- Implementation Requirements*
- The implementation shall give a warning message for an unrecognized **pragma** name. 13
- Ramification:** An implementation is also allowed to have modes in which a warning message is suppressed, or in which the presence of an unrecognized **pragma** is a compile-time error. 13.a
- Implementation Permissions*
- An implementation may provide implementation-defined **pragmas**; the name of an implementation-defined **pragma** shall differ from those of the language-defined **pragmas**. 14
- Implementation defined:** Implementation-defined **pragmas**. 14.a
- Ramification:** The semantics of implementation-defined **pragmas**, and any associated rules (such as restrictions on their placement or arguments), are, of course, implementation defined. Implementation-defined **pragmas** may have run-time effects. 14.b
- An implementation may ignore an unrecognized **pragma** even if it violates some of the Syntax Rules, if detecting the syntax error is too complex. 15

- 15.a **Reason:** Many compilers use extra post-parsing checks to enforce the syntax rules, since the Ada syntax rules are not LR(k) (for any k). (The grammar is ambiguous, in fact.) This paragraph allows them to ignore an unrecognized pragma, without having to perform such post-parsing checks.

Implementation Advice

- 16/3 {AI05-0163-1} Normally, implementation-defined pragmas should have no semantic effect for error-free programs; that is, if the implementation-defined pragmas in a working program are replaced with unrecognized pragmas, the program should still be legal, and should still have the same semantics.

- 16.a.1/2 **Implementation Advice:** Implementation-defined pragmas should have no semantic effect for error-free programs.

- 16.a **Ramification:** Note that “semantics” is not the same as “effect;” as explained in 1.1.3, the semantics defines a set of possible effects.

- 16.b Note that adding a pragma to a program might cause an error (either at compile time or at run time). On the other hand, if the language-specified semantics for a feature are in part implementation defined, it makes sense to support pragmas that control the feature, and that have real semantics; thus, this paragraph is merely a recommendation.

- 17 Normally, an implementation should not define pragmas that can make an illegal program legal, except as follows:

- 18/3 • {AI05-0229-1} A pragma used to complete a declaration;

- 18.a/3 **Discussion:** {AI05-0229-1} There are no language-defined pragmas which can be completions; pragma Import was defined this way in Ada 95 and Ada 2005, but in Ada 2012 pragma Import just sets aspect Import which disallows having any completion.

- 19 • A pragma used to configure the environment by adding, removing, or replacing library_items.

- 19.a.1/2 **Implementation Advice:** Implementation-defined pragmas should not make an illegal program legal, unless they complete a declaration or configure the library_items in an environment.

- 19.a **Ramification:** For example, it is OK to support Interface, System_Name, Storage_Unit, and Memory_Size pragmas for upward compatibility reasons, even though all of these pragmas can make an illegal program legal. (The latter three can affect legality in a rather subtle way: They affect the value of named numbers in System, and can therefore affect the legality in cases where static expressions are required.)

- 19.b On the other hand, adding implementation-defined pragmas to a legal program can make it illegal. For example, a common kind of implementation-defined pragma is one that promises some property that allows more efficient code to be generated. If the promise is a lie, it is best if the user gets an error message.

Incompatibilities With Ada 83

- 19.c In Ada 83, “bad” pragmas are ignored. In Ada 95, they are illegal, except in the case where the name of the pragma itself is not recognized by the implementation.

Extensions to Ada 83

- 19.d Implementation-defined pragmas may affect the legality of a program.

Wording Changes from Ada 83

- 19.e Implementation-defined pragmas may affect the run-time semantics of the program. This was always true in Ada 83 (since it was not explicitly forbidden by RM83), but it was not clear, because there was no definition of “executing” or “elaborating” a pragma.

Extensions to Ada 2005

- 19.f/3 {AI05-0163-1} **Correction:** Allow pragmas in place of a statement, even if there are no other statements in a sequence_of_statements.

- 19.g/3 {AI05-0272-1} Identifiers specific to a pragma can be reserved words.

- 19.h/3 {AI05-0290-1} Pragma arguments can be identified with aspect_marks; this allows identifier'Class in this context. As usual, this is only allowed if specifically allowed by a particular pragma.

Wording Changes from Ada 2005

- 19.i/3 {AI05-0100-1} **Correction:** Clarified where pragmas are (and are not) allowed.

Syntax

- The forms of List, Page, and Optimize pragmas are as follows: 20
- pragma** List(identifier); 21
- pragma** Page; 22
- pragma** Optimize(identifier); 23
- [Other pragmas are defined throughout this International Standard, and are summarized in Annex L.] 24
- Ramification:** The language-defined pragmas are supported by every implementation, although “supporting” some of them (for example, Inline) requires nothing more than checking the arguments, since they act only as advice to the implementation. 24.a

Static Semantics

- A **pragma** List takes one of the identifiers On or Off as the single argument. This pragma is allowed anywhere a **pragma** is allowed. It specifies that listing of the compilation is to be continued or suspended until a List pragma with the opposite argument is given within the same compilation. The pragma itself is always listed if the compiler is producing a listing. 25
- A **pragma** Page is allowed anywhere a **pragma** is allowed. It specifies that the program text which follows the pragma should start on a new page (if the compiler is currently producing a listing). 26
- A **pragma** Optimize takes one of the identifiers Time, Space, or Off as the single argument. This pragma is allowed anywhere a **pragma** is allowed, and it applies until the end of the immediately enclosing declarative region, or for a pragma at the place of a compilation_unit, to the end of the compilation. It gives advice to the implementation as to whether time or space is the primary optimization criterion, or that optional optimizations should be turned off. [It is implementation defined how this advice is followed.] 27
- Implementation defined:** Effect of pragma Optimize. 27.a
- Discussion:** For example, a compiler might use Time vs. Space to control whether generic instantiations are implemented with a macro-expansion model, versus a shared-generic-body model. 27.b
- We don't define what constitutes an “optimization” — in fact, it cannot be formally defined in the context of Ada. One compiler might call something an optional optimization, whereas another compiler might consider that same thing to be a normal part of code generation. Thus, the programmer cannot rely on this pragma having any particular portable effect on the generated code. Some compilers might even ignore the pragma altogether. 27.c

Examples

- Examples of pragmas:* 28
- ```
{AI95-00433-01} {AI05-0229-1} pragma List(Off); -- turn off listing generation 29/3
pragma Optimize(Off); -- turn off optional optimizations
pragma Pure(Rational_Numbers); -- set categorization for package
pragma Assert(Exists(File_Name),
 Message => "Nonexistent file"); -- assert file exists
```

*Extensions to Ada 83*

- The Optimize pragma now allows the identifier Off to request that normal optimization be turned off. 29.a
- An Optimize pragma may appear anywhere pragmas are allowed. 29.b

*Wording Changes from Ada 83*

- We now describe the pragmas Page, List, and Optimize here, to act as examples, and to remove the normative material from Annex L, “Language-Defined Pragmas”, so it can be entirely an informative annex. 29.c

*Wording Changes from Ada 95*

- {AI95-00433-01} Updated the example of named pragma parameters, because the second parameter of pragma Suppress is obsolescent. 29.d/2

29.e/3 {AI05-0229-1} Updated the example of pragmas, because both pragmas Inline and Import are obsolescent.

## 2.9 Reserved Words

### Syntax

1/1 *This paragraph was deleted.*

2/3 {AI95-00284-02} {AI95-00395-01} {AI05-0091-1} The following are the *reserved words*. Within a program, some or all of the letters of a reserved word may be in upper case.

2.a **Discussion:** Reserved words have special meaning in the syntax. In addition, certain reserved words are used as attribute names.

2.b The syntactic category `identifier` no longer allows reserved words. We have added the few reserved words that are legal explicitly to the syntax for `attribute_reference`. Allowing `identifier` to include reserved words has been a source of confusion for some users, and differs from the way they are treated in the C and Pascal language definitions.

### NOTES

3 7 The reserved words appear in **lower case boldface** in this International Standard, except when used in the designator of an attribute (see 4.1.4). Lower case boldface is also used for a reserved word in a `string_literal` used as an `operator_symbol`. This is merely a convention — programs may be written in whatever typeface is desired and available.

### Incompatibilities With Ada 83

3.a The following words are not reserved in Ada 83, but are reserved in Ada 95: **abstract**, **aliased**, **protected**, **requeue**, **tagged**, **until**.

### Wording Changes from Ada 83

3.b/3 {AI05-0299-1} The subclause entitled “Allowed Replacements of Characters” has been moved to Annex J, “Obsolescent Features”.

*Incompatibilities With Ada 95*

{AI95-00284-02} The following words are not reserved in Ada 95, but are reserved in Ada 2005: **interface**, **overriding**, **synchronized**. A special allowance is made for **pragma** Interface (see J.12). Uses of these words as identifiers will need to be changed, but we do not expect them to be common. 3.c/2

*Wording Changes from Ada 95*

{AI95-00395-01} The definition of upper case equivalence has been modified to allow identifiers using all of the characters of ISO 10646. This change has no effect on the character sequences that are reserved words, but does make some unusual sequences of characters illegal. 3.d/2

*Incompatibilities With Ada 2005*

{AI05-0091-1} **Correction:** Removed **other\_format** characters from reserved words in order to be compatible with the latest Unicode recommendations. This change can only affect programs written for original Ada 2005, and there is little reason to put **other\_format** characters into reserved words in the first place, so there should be very few such programs. 3.e/3

{AI05-0176-1} The following word is not reserved in Ada 2005, but is reserved in Ada 2012: **some**. Uses of this word as an identifier will need to be changed, but we do not expect them to be common. 3.f/3

## 3 Declarations and Types

{AI05-0299-1} This clause describes the types in the language and the rules for declaring constants, variables, and named numbers. 1/3

### 3.1 Declarations

The language defines several kinds of named *entities* that are declared by declarations. The entity's *name* is defined by the declaration, usually by a `defining_identifier`, but sometimes by a `defining_character_literal` or `defining_operator_symbol`. 1

There are several forms of declaration. A `basic_declaration` is a form of declaration defined as follows. 2

*Syntax*

```
{AI95-00348-01} {AI05-0177-1} basic_declaration ::=
 type_declaration | subtype_declaration
 | object_declaration | number_declaration
 | subprogram_declaration | abstract_subprogram_declaration
 | null_procedure_declaration | expression_function_declaration
 | package_declaration | renaming_declaration
 | exception_declaration | generic_declaration
 | generic_instantiation
```

```
defining_identifier ::= identifier 4
```

*Static Semantics*

A *declaration* is a language construct that associates a name with (a view of) an entity. A declaration may appear explicitly in the program text (an *explicit* declaration), or may be supposed to occur at a given place in the text as a consequence of the semantics of another construct (an *implicit* declaration). 5

**Discussion:** An implicit declaration generally declares a predefined or inherited operation associated with the definition of a type. This term is used primarily when allowing explicit declarations to override implicit declarations, as part of a type declaration. 5.a

{AI95-00318-02} {AI05-0255-1} {AI05-0277-1} Each of the following is defined to be a declaration: any `basic_declaration`; an `enumeration_literal_specification`; a `discriminant_specification`; a `component_declaration`; a `loop_parameter_specification`; an `iterator_specification`; a `parameter_specification`; a `subprogram_body`; an `extended_return_object_declaration`; an `entry_declaration`; an `entry_index_specification`; a `choice_parameter_specification`; a `generic_formal_parameter_declaration`. 6/3

**Discussion:** This list (when `basic_declaration` is expanded out) contains all syntactic categories that end in `"_declaration"` or `"_specification"`, except for `program_unit_specifications`. Moreover, it contains `subprogram_body`. A `subprogram_body` is a declaration, whether or not it completes a previous declaration. This is a bit strange, `subprogram_body` is not part of the syntax of `basic_declaration` or `library_unit_declaration`. A `renaming-as-body` is considered a declaration. An `accept_statement` is not considered a declaration. Completions are sometimes declarations, and sometimes not. 6.a

All declarations contain a *definition* for a *view* of an entity. A view consists of an identification of the entity (the entity *of* the view), plus view-specific characteristics that affect the use of the entity through that view (such as mode of access to an object, formal parameter names and defaults for a subprogram, or visibility to components of a type). In most cases, a declaration also contains the definition for the entity itself (a `renaming_declaration` is an example of a declaration that does not define a new entity, but instead defines a view of an existing entity (see 8.5)). 7

**Glossary entry:** A view of an entity reveals some or all of the properties of the entity. A single entity may have multiple views. 7.a/2

- 7.b **Discussion:** Most declarations define a view (of some entity) whose view-specific characteristics are unchanging for the life of the view. However, subtypes are somewhat unusual in that they inherit characteristics from whatever view of their type is currently visible. Hence, a subtype is not a *view* of a type; it is more of an indirect reference. By contrast, a private type provides a single, unchanging (partial) view of its full type.
- 7.1/3 {AI05-0080-1} When it is clear from context, the term *object* is used in place of *view of an object*. Similarly, the terms *type* and *subtype* are used in place of *view of a type* and *view of a subtype*, respectively.
- 7.c/3 **Discussion:** Rules interpreted at compile time generally refer to views of entities, rather than the entities themselves. This is necessary to preserve privacy; characteristics that are not visible should not be used in compile-time rules. Thus, Static Semantics and Legality Rules generally implicitly have “view of”. Legality Rules that need to look into the private part are the exception to this interpretation.
- 7.d/3 On the other hand, run-time rules can work either way, so “view of” should not be assumed in Dynamic Semantics rules.
- 8 For each declaration, the language rules define a certain region of text called the *scope* of the declaration (see 8.2). Most declarations associate an identifier with a declared entity. Within its scope, and only there, there are places where it is possible to use the identifier to refer to the declaration, the view it defines, and the associated entity; these places are defined by the visibility rules (see 8.3). At such places the identifier is said to be a *name* of the entity (the *direct\_name* or *selector\_name*); the name is said to *denote* the declaration, the view, and the associated entity (see 8.6). The declaration is said to *declare* the name, the view, and in most cases, the entity itself.
- 9 As an alternative to an identifier, an enumeration literal can be declared with a *character\_literal* as its name (see 3.5.1), and a function can be declared with an *operator\_symbol* as its name (see 6.1).
- 10 The syntax rules use the terms *defining\_identifier*, *defining\_character\_literal*, and *defining\_operator\_symbol* for the defining occurrence of a name; these are collectively called *defining names*. The terms *direct\_name* and *selector\_name* are used for usage occurrences of identifiers, *character\_literals*, and *operator\_symbols*. These are collectively called *usage names*.
- 10.a **To be honest:** The terms *identifier*, *character\_literal*, and *operator\_symbol* are used directly in contexts where the normal visibility rules do not apply (such as the identifier that appears after the **end** of a *task\_body*). Analogous conventions apply to the use of *designator*, which is the collective term for *identifier* and *operator\_symbol*.

#### *Dynamic Semantics*

- 11 The process by which a construct achieves its run-time effect is called *execution*. This process is also called *elaboration* for declarations and *evaluation* for expressions. One of the terms execution, elaboration, or evaluation is defined by this International Standard for each construct that has a run-time effect.
- 11.a **Glossary entry:** The process by which a construct achieves its run-time effect is called *execution*. Execution of a declaration is also called *elaboration*. Execution of an expression is also called *evaluation*.
- 11.b **To be honest:** The term elaboration is also used for the execution of certain constructs that are not declarations, and the term evaluation is used for the execution of certain constructs that are not expressions. For example, *subtype\_indications* are elaborated, and *ranges* are evaluated.
- 11.c For bodies, execution and elaboration are both explicitly defined. When we refer specifically to the execution of a body, we mean the explicit definition of execution for that kind of body, not its elaboration.
- 11.d **Discussion:** Technically, “the execution of a declaration” and “the elaboration of a declaration” are synonymous. We use the term “elaboration” of a construct when we know the construct is elaborable. When we are talking about more arbitrary constructs, we use the term “execution”. For example, we use the term “erroneous execution”, to refer to any erroneous execution, including erroneous elaboration or evaluation.
- 11.e When we explicitly define evaluation or elaboration for a construct, we are implicitly defining execution of that construct.
- 11.f We also use the term “execution” for things like *statements*, which are executable, but neither elaborable nor evaluable. We considered using the term “execution” only for nonelaborable, nonevaluable constructs, and defining the term “action” to mean what we have defined “execution” to mean. We rejected this idea because we thought three

|                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |          |
|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|----------|
| terms that mean the same thing was enough — four would be overkill. Thus, the term "action" is used only informally in the standard (except where it is defined as part of a larger term, such as "protected action").                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |          |
| <b>Glossary entry:</b> The process by which a declaration achieves its run-time effect is called elaboration. Elaboration is one of the forms of execution.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              | 11.f.1/2 |
| <b>Glossary entry:</b> The process by which an expression achieves its run-time effect is called evaluation. | <b>To be honest:</b> A construct is <i>elaborable</i> if elaboration is defined for it. A construct is <i>evaluable</i> if evaluation is defined for it. A construct is <i>executable</i> if execution is defined for it.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                | 11.g     |
| <b>Discussion:</b> Don't confuse “elaborable” with “preelaborable” (defined in 10.2.1).                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  | 11.h     |
| {AI95-00114-01} Evaluation of an evaluable construct produces a result that is either a value, a denotation, or a range. The following are evaluable: <code>expression</code> ; <code>name_prefix</code> ; <code>range</code> ; <code>entry_index_specification</code> ; and possibly <code>discrete_range</code> . The last one is curious — RM83 uses the term “evaluation of a <code>discrete_range</code> ,” but never defines it. One might presume that the evaluation of a <code>discrete_range</code> consists of the evaluation of the <code>range</code> or the <code>subtype_indication</code> , depending on what it is. But <code>subtype_indications</code> are not evaluated; they are elaborated.                                                                                                                                                                                        | 11.i/2   |
| Intuitively, an <i>executable</i> construct is one that has a defined run-time effect (which may be null). Since execution includes elaboration and evaluation as special cases, all elaborable and all evaluable constructs are also executable. Hence, most constructs in Ada are executable. An important exception is that the constructs inside a generic unit are not executable directly, but rather are used as a template for (generally) executable constructs in instances of the generic.                                                                                                                                                                                                                                                                                                                                                                                                    | 11.j     |
| NOTES                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |          |
| 1 At compile time, the declaration of an entity <i>declares</i> the entity. At run time, the elaboration of the declaration <i>creates</i> the entity.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   | 12       |
| <b>Ramification:</b> Syntactic categories for declarations are named either <i>entity_declaration</i> (if they include a trailing semicolon) or <i>entity_specification</i> (if not).                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    | 12.a     |
| The various kinds of named entities that can be declared are as follows: an object (including components and parameters), a named number, a type (the name always refers to its first subtype), a subtype, a subprogram (including enumeration literals and operators), a single entry, an entry family, a package, a protected or task unit (which corresponds to either a type or a single object), an exception, a generic unit, a label, and the name of a statement.                                                                                                                                                                                                                                                                                                                                                                                                                                | 12.b     |
| Identifiers are also associated with names of pragmas, arguments to pragmas, and with attributes, but these are not user-definable.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      | 12.c     |
| <i>Wording Changes from Ada 83</i>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |          |
| The syntax rule for <code>defining_identifier</code> is new. It is used for the defining occurrence of an <code>identifier</code> . Usage occurrences use the <code>direct_name</code> or <code>selector_name</code> syntactic categories. Each occurrence of an <code>identifier</code> (or <code>simple_name</code> ), <code>character_literal</code> , or <code>operator_symbol</code> in the Ada 83 syntax rules is handled as follows in Ada 95:                                                                                                                                                                                                                                                                                                                                                                                                                                                    | 12.d     |
| <ul style="list-style-type: none"> <li>• It becomes a <code>defining_identifier</code>, <code>defining_character_literal</code>, or <code>defining_operator_symbol</code> (or some syntactic category composed of these), to indicate a defining occurrence;</li> <li>• {AI05-0299-1} It becomes a <code>direct_name</code>, in usage occurrences where the usage is required (in Clause 8) to be directly visible;</li> <li>• {AI05-0299-1} It becomes a <code>selector_name</code>, in usage occurrences where the usage is required (in Clause 8) to be visible but not necessarily directly visible;</li> <li>• It remains an <code>identifier</code>, <code>character_literal</code>, or <code>operator_symbol</code>, in cases where the visibility rules do not apply (such as the <code>designator</code> that appears after the <code>end</code> of a <code>subprogram_body</code>).</li> </ul> | 12.e     |
| For declarations that come in “two parts” (program unit declaration plus body, private or incomplete type plus full type, deferred constant plus full constant), we consider both to be defining occurrences. Thus, for example, the syntax for <code>package_body</code> uses <code>defining_identifier</code> after the reserved word <code>body</code> , as opposed to <code>direct_name</code> .                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     | 12.i     |
| The defining occurrence of a statement name is in its implicit declaration, not where it appears in the program text. Considering the statement name itself to be the defining occurrence would complicate the visibility rules.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         | 12.j     |
| The phrase “visible by selection” is not used in Ada 95. It is subsumed by simply “visible” and the Name Resolution Rules for <code>selector_names</code> .                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              | 12.k     |
| {AI05-0299-1} (Note that in Ada 95, a declaration is visible at all places where one could have used a <code>selector_name</code> , not just at places where a <code>selector_name</code> was actually used. Thus, the places where a declaration is directly visible are a subset of the places where it is visible. See Clause 8 for details.)                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         | 12.l/3   |
| We use the term “declaration” to cover <code>_specifications</code> that declare (views of) objects, such as <code>parameter_specifications</code> . In Ada 83, these are referred to as a “form of declaration,” but it is not entirely clear that they are considered simply “declarations.”                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           | 12.m     |

- 12.n/3 {AI05-0299-1} RM83 contains an incomplete definition of "elaborated" in this subclause: it defines "elaborated" for declarations, `declarative_parts`, `declarative_items` and `compilation_units`, but "elaboration" is defined elsewhere for various other constructs. To make matters worse, Ada 95 has a different set of elaborable constructs. Instead of correcting the list, it is more maintainable to refer to the term "elaborable," which is defined in a distributed manner.
- 12.o RM83 uses the term "has no other effect" to describe an elaboration that doesn't do anything except change the state from not-yet-elaborated to elaborated. This was a confusing wording, because the answer to "other than what?" was to be found many pages away. In Ada 95, we change this wording to "has no effect" (for things that truly do nothing at run time), and "has no effect other than to establish that so-and-so can happen without failing the `Elaboration_Check`" (for things where it matters).
- 12.p We make it clearer that the term "execution" covers elaboration and evaluation as special cases. This was implied in RM83. For example, "erroneous execution" can include any execution, and RM83-9.4(3) has, "The task designated by any other task object depends on the master whose execution creates the task object;" the elaboration of the master's `declarative_part` is doing the task creation.

*Wording Changes from Ada 95*

- 12.q/2 {AI95-00318-02} Added `extended_return_statement` to the list of declarations.
- 12.r/2 {AI95-00348-01} Added null procedures (see 6.7) to the syntax.

*Wording Changes from Ada 2005*

- 12.s/3 {AI05-0177-1} Added expression functions (see 6.8) to the syntax.

## 3.2 Types and Subtypes

*Static Semantics*

- 1 A *type* is characterized by a set of values, and a set of *primitive operations* which implement the fundamental aspects of its semantics. An *object* of a given type is a run-time entity that contains (has) a value of the type.
- 1.a/2 **Glossary entry:** Each object has a type. A *type* has an associated set of values, and a set of *primitive operations* which implement the fundamental aspects of its semantics. Types are grouped into *categories*. Most language-defined categories of types are also *classes* of types.
- 1.b/3 **Glossary entry:** A subtype is a type together with optional constraints, null exclusions, and predicates, which constrain the values of the subtype to satisfy certain conditions. The values of a subtype are a subset of the values of its type.
- 2/2 {AI95-00442-01} Types are grouped into *categories* of types. There exist several *language-defined categories* of types (see NOTES below), reflecting the similarity of their values and primitive operations. [Most categories of types form *classes* of types.] *Elementary* types are those whose values are logically indivisible; *composite* types are those whose values are composed of *component* values.
- 2.a/2 **Proof:** {AI95-00442-01} The formal definition of *category* and *class* is found in 3.4.
- 2.b/2 **Glossary entry:** A class is a set of types that is closed under derivation, which means that if a given type is in the class, then all types derived from that type are also in the class. The set of types of a class share common properties, such as their primitive operations.
- 2.b.1/2 **Glossary entry:** A category of types is a set of types with one or more common properties, such as primitive operations. A category of types that is closed under derivation is also known as a *class*.
- 2.c **Glossary entry:** An elementary type does not have components.
- 2.d/2 **Glossary entry:** A composite type may have components.
- 2.e **Glossary entry:** A scalar type is either a discrete type or a real type.
- 2.f **Glossary entry:** An access type has values that designate aliased objects. Access types correspond to "pointer types" or "reference types" in some other languages.
- 2.g **Glossary entry:** A discrete type is either an integer type or an enumeration type. Discrete types may be used, for example, in `case_statements` and as array indices.
- 2.h **Glossary entry:** A real type has values that are approximations of the real numbers. Floating point and fixed point types are real types.

- Glossary entry:** Integer types comprise the signed integer types and the modular types. A signed integer type has a base range that includes both positive and negative numbers, and has operations that may raise an exception when the result is outside the base range. A modular type has a base range whose lower bound is zero, and has operations with “wraparound” semantics. Modular types subsume what are called “unsigned types” in some other languages. 2.i
- Glossary entry:** An enumeration type is defined by an enumeration of its values, which may be named by identifiers or character literals. 2.j
- Glossary entry:** A character type is an enumeration type whose values include characters. 2.k
- Glossary entry:** A record type is a composite type consisting of zero or more named components, possibly of different types. 2.l
- Glossary entry:** A record extension is a type that extends another type by adding additional components. 2.m
- Glossary entry:** An array type is a composite type whose components are all of the same type. Components are selected by indexing. 2.n
- Glossary entry:** A task type is a composite type used to represent active entities which execute concurrently and which can communicate via queued task entries. The top-level task of a partition is called the environment task. 2.o/2
- Glossary entry:** A protected type is a composite type whose components are accessible only through one of its protected operations which synchronize concurrent access by multiple tasks. 2.p/2
- Glossary entry:** A private type gives a view of a type that reveals only some of its properties. The remaining properties are provided by the full view given elsewhere. Private types can be used for defining abstractions that hide unnecessary details from their clients. 2.q/2
- Glossary entry:** A private extension is a type that extends another type, with the additional properties hidden from its clients. 2.r/2
- Glossary entry:** An incomplete type gives a view of a type that reveals only some of its properties. The remaining properties are provided by the full view given elsewhere. Incomplete types can be used for defining recursive data structures. 2.s/2
- The elementary types are the *scalar* types (*discrete* and *real*) and the *access* types (whose values provide access to objects or subprograms). Discrete types are either *integer* types or are defined by enumeration of their values (*enumeration* types). Real types are either *floating point* types or *fixed point* types. 3
- {AI95-00251-01} {AI95-00326-01} The composite types are the *record* types, *record extensions*, *array* types, *interface* types, *task* types, and *protected* types. 4/2
- This paragraph was deleted. {AI95-00442-01}* 4.a/2
- {AI95-00326-01} There can be multiple views of a type with varying sets of operations. [An *incomplete* type represents an incomplete view (see 3.10.1) of a type with a very restricted usage, providing support for recursive data structures. A *private* type or *private extension* represents a partial view (see 7.3) of a type, providing support for data abstraction. The full view (see 3.2.1) of a type represents its complete definition.] An incomplete or partial view is considered a composite type[, even if the full view is not]. 4.1/2
- Proof:** {AI05-0299-1} The real definitions of the views are in the referenced subclauses. 4.b/3
- {AI95-00326-01} Certain composite types (and views thereof) have special components called *discriminants* whose values affect the presence, constraints, or initialization of other components. Discriminants can be thought of as parameters of the type. 5/2
- {AI95-00366-01} The term *subcomponent* is used in this International Standard in place of the term component to indicate either a component, or a component of another subcomponent. Where other subcomponents are excluded, the term component is used instead. Similarly, a *part* of an object or value is used to mean the whole object or value, or any set of its subcomponents. The terms component, subcomponent, and part are also applied to a type meaning the component, subcomponent, or part of objects and values of the type. 6/2
- Discussion:** The definition of “part” here is designed to simplify rules elsewhere. By design, the intuitive meaning of “part” will convey the correct result to the casual reader, while this formalistic definition will answer the concern of the compiler-writer. 6.a

- 6.b We use the term “part” when talking about the parent part, ancestor part, or extension part of a type extension. In contexts such as these, the part might represent an empty set of subcomponents (e.g. in a null record extension, or a nonnull extension of a null record). We also use “part” when specifying rules such as those that apply to an object with a “controlled part” meaning that it applies if the object as a whole is controlled, or any subcomponent is.
- 7/2 {AI95-00231-01} The set of possible values for an object of a given type can be subjected to a condition that is called a *constraint* (the case of a *null constraint* that specifies no restriction is also included); the rules for which values satisfy a given kind of constraint are given in 3.5 for *range\_constraints*, 3.6.1 for *index\_constraints*, and 3.7.1 for *discriminant\_constraints*. The set of possible values for an object of an access type can also be subjected to a condition that excludes the null value (see 3.10).
- 8/2 {AI95-00231-01} {AI95-00415-01} A *subtype* of a given type is a combination of the type, a constraint on values of the type, and certain attributes specific to the subtype. The given type is called the *type of the subtype*. Similarly, the associated constraint is called the *constraint of the subtype*. The set of values of a subtype consists of the values of its type that satisfy its constraint and any exclusion of the null value. Such values *belong* to the subtype.
- 8.a **Discussion:** We make a strong distinction between a type and its subtypes. In particular, a type is *not* a subtype of itself. There is no constraint associated with a type (not even a null one), and type-related attributes are distinct from subtype-specific attributes.
- 8.b **Discussion:** We no longer use the term "base type." All types were "base types" anyway in Ada 83, so the term was redundant, and occasionally confusing. In the RM95 we say simply "the type of the subtype" instead of "the base type of the subtype."
- 8.c **Ramification:** The value subset for a subtype might be empty, and need not be a proper subset.
- 8.d/2 **To be honest:** {AI95-00442-01} Any name of a category of types (such as “discrete”, “real”, or “limited”) is also used to qualify its subtypes, as well as its objects, values, declarations, and definitions, such as an “integer type declaration” or an “integer value.” In addition, if a term such as “parent subtype” or “index subtype” is defined, then the corresponding term for the type of the subtype is “parent type” or “index type.”
- 8.e **Discussion:** We use these corresponding terms without explicitly defining them, when the meaning is obvious.
- 9 A subtype is called an *unconstrained* subtype if its type has unknown discriminants, or if its type allows range, index, or discriminant constraints, but the subtype does not impose such a constraint; otherwise, the subtype is called a *constrained* subtype (since it has no unconstrained characteristics).
- 9.a **Discussion:** In an earlier version of Ada 9X, "constrained" meant "has a nonnull constraint." However, we changed to this definition since we kept having to special case composite non-array/nondiscriminated types. It also corresponds better to the (now obsolescent) attribute 'Constrained.
- 9.b For scalar types, “constrained” means “has a nonnull constraint”. For composite types, in implementation terms, “constrained” means that the size of all objects of the subtype is the same, assuming a typical implementation model.
- 9.c Class-wide subtypes are always unconstrained.
- NOTES
- 10/2 2 {AI95-00442-01} Any set of types can be called a “category” of types, and any set of types that is closed under derivation (see 3.4) can be called a “class” of types. However, only certain categories and classes are used in the description of the rules of the language — generally those that have their own particular set of primitive operations (see 3.2.3), or that correspond to a set of types that are matched by a given kind of generic formal type (see 12.5). The following are examples of “interesting” *language-defined classes*: elementary, scalar, discrete, enumeration, character, boolean, integer, signed integer, modular, real, floating point, fixed point, ordinary fixed point, decimal fixed point, numeric, access, access-to-object, access-to-subprogram, composite, array, string, (untagged) record, tagged, task, protected, nonlimited. Special syntax is provided to define types in each of these classes. In addition to these classes, the following are examples of “interesting” *language-defined categories*: abstract, incomplete, interface, limited, private, record.
- 10.a **Discussion:** A *value* is a run-time entity with a given type which can be assigned to an object of an appropriate subtype of the type. An *operation* is a program entity that operates on zero or more operands to produce an effect, or yield a result, or both.
- 10.b/2 **Ramification:** {AI95-00442-01} Note that a type's category (and class) depends on the place of the reference — a private type is composite outside and possibly elementary inside. It's really the *view* that is elementary or composite. Note that although private types are composite, there are some properties that depend on the corresponding full view — for example, parameter passing modes, and the constraint checks that apply in various places.

|                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |                                                                   |
|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------|
| <p>{AI95-00345-01} {AI95-00442-01} Every property of types forms a category, but not every property of types represents a class. For example, the set of all abstract types does not form a class, because this set is not closed under derivation. Similarly, the set of all interface types does not form a class.</p> <p>{AI95-00442-01} The set of limited types does not form a class (since nonlimited types can inherit from limited interfaces), but the set of nonlimited types does. The set of tagged record types and the set of tagged private types do not form a class (because each of them can be extended to create a type of the other category); that implies that the set of record types and the set of private types also do not form a class (even though untagged record types and untagged private types do form a class). In all of these cases, we can talk about the category of the type; for instance, we can talk about the “category of limited types”.</p> <p>{AI95-00442-01} Normatively, the <i>language-defined classes</i> are those that are defined to be inherited on derivation by 3.4; other properties either aren't interesting or form categories, not classes.</p> <p>{AI95-00442-01} These language-defined categories are organized like this:</p> <ul style="list-style-type: none"> <li>{AI95-00345-01} all types <ul style="list-style-type: none"> <li>elementary <ul style="list-style-type: none"> <li>scalar <ul style="list-style-type: none"> <li>discrete <ul style="list-style-type: none"> <li>enumeration <ul style="list-style-type: none"> <li>character</li> <li>boolean</li> <li>other enumeration</li> </ul> </li> <li>integer <ul style="list-style-type: none"> <li>signed integer</li> <li>modular integer</li> </ul> </li> <li>real <ul style="list-style-type: none"> <li>floating point</li> <li>fixed point <ul style="list-style-type: none"> <li>ordinary fixed point</li> <li>decimal fixed point</li> </ul> </li> </ul> </li> </ul> </li> <li>access <ul style="list-style-type: none"> <li>access-to-object</li> <li>access-to-subprogram</li> </ul> </li> <li>composite <ul style="list-style-type: none"> <li>untagged <ul style="list-style-type: none"> <li>array <ul style="list-style-type: none"> <li>string</li> <li>other array</li> </ul> </li> <li>record</li> <li>task</li> <li>protected</li> <li>tagged (including interfaces) <ul style="list-style-type: none"> <li>nonlimited tagged record</li> <li>limited tagged <ul style="list-style-type: none"> <li>limited tagged record</li> <li>synchronized tagged <ul style="list-style-type: none"> <li>tagged task</li> <li>tagged protected</li> </ul> </li> </ul> | <p>10.c/2</p> <p>10.d/2</p> <p>10.e/2</p> <p>11/2</p> <p>12/2</p> |
| <p>{AI95-00345-01} {AI95-00442-01} There are other categories, such as “numeric” and “discriminated”, which represent other categorization dimensions, but do not fit into the above strictly hierarchical picture.</p> <p><b>Discussion:</b> {AI95-00345-01} {AI95-00442-01} Note that this is also true for some categories mentioned in the chart. The category “task” includes both untagged tasks and tagged tasks. Similarly for “protected”, “limited”, and “nonlimited” (note that limited and nonlimited are not shown for untagged composite types).</p> <p style="text-align: center;"><i>Wording Changes from Ada 83</i></p> <p>{AI05-0299-1} This subclause now precedes the subclauses on objects and named numbers, to cut down on the number of forward references.</p> <p>We have dropped the term “base type” in favor of simply “type” (all types in Ada 83 were “base types” so it wasn't clear when it was appropriate/necessary to say “base type”). Given a subtype S of a type T, we call T the “type of the subtype S.”</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  | <p>13/2</p> <p>13.a.1/2</p> <p>13.a/3</p> <p>13.b</p>             |

*Wording Changes from Ada 95*

- 13.c/2 {AI95-00231-01} Added a mention of null exclusions when we're talking about constraints (these are not constraints, but they are similar).
- 13.d/2 {AI95-00251-01} Defined an interface type to be a composite type.
- 13.e/2 {AI95-00326-01} Revised the wording so that it is clear that an incomplete view is similar to a partial view in terms of the language.
- 13.f/2 {AI95-00366-01} Added a definition of component of a type, subcomponent of a type, and part of a type. These are commonly used in the standard, but they were not previously defined.
- 13.g/3 {AI95-00442-01} {AI05-0299-1} Reworded most of this subclause to use category rather than class, since so many interesting properties are not, strictly speaking, classes. Moreover, there was no normative description of exactly which properties formed classes, and which did not. The real definition of class, along with a list of properties, is now in 3.4.

### 3.2.1 Type Declarations

- 1 A `type_declaration` declares a type and its first subtype.

*Syntax*

- 2 `type_declaration ::= full_type_declaration`  
   | `incomplete_type_declaration`  
   | `private_type_declaration`  
   | `private_extension_declaration`
- 3/3 {AI05-0183-1} `full_type_declaration ::=`  
   `type` `defining_identifier` [`known_discriminant_part`] `is` `type_definition`  
   [`aspect_specification`];  
   | `task_type_declaration`  
   | `protected_type_declaration`
- 4/2 {AI95-00251-01} `type_definition ::=`  
   `enumeration_type_definition` | `integer_type_definition`  
   | `real_type_definition` | `array_type_definition`  
   | `record_type_definition` | `access_type_definition`  
   | `derived_type_definition` | `interface_type_definition`

*Legality Rules*

- 5 A given type shall not have a subcomponent whose type is the given type itself.

*Static Semantics*

- 6 The `defining_identifier` of a `type_declaration` denotes the *first subtype* of the type. The `known_discriminant_part`, if any, defines the discriminants of the type (see 3.7, “Discriminants”). The remainder of the `type_declaration` defines the remaining characteristics of (the view of) the type.
- 7/2 {AI95-00230-01} A type defined by a `type_declaration` is a *named* type; such a type has one or more nameable subtypes. Certain other forms of declaration also include type definitions as part of the declaration for an object. The type defined by such a declaration is *anonymous* — it has no nameable subtypes. For explanatory purposes, this International Standard sometimes refers to an anonymous type by a pseudo-name, written in italics, and uses such pseudo-names at places where the syntax normally requires an identifier. For a named type whose first subtype is T, this International Standard sometimes refers to the type of T as simply “the type T”.
- 7.a/2 **Ramification:** {AI95-00230-01} The only user-defined types that can be anonymous in the above sense are array, access, task, and protected types. An anonymous array, task, or protected type can be defined as part of an `object_declaration`. An anonymous access type can be defined as part of numerous other constructs.

{AI95-00230-01} {AI95-00326-01} A named type that is declared by a `full_type_declaration`, or an anonymous type that is defined by an `access_definition` or as part of declaring an object of the type, is called a *full type*. The declaration of a full type also declares the *full view* of the type. The `type_definition`, `task_definition`, `protected_definition`, or `access_definition` that defines a full type is called a *full type definition*. [Types declared by other forms of `type_declaration` are not separate types; they are partial or incomplete views of some full type.] 8/2

**To be honest:** Class-wide, universal, and root numeric types are full types. 8.a

**Reason:** {AI95-00230-01} We need to mention `access_definition` separately, as it may occur in renames, which do not declare objects. 8.b/2

The definition of a type implicitly declares certain *predefined operators* that operate on the type, according to what classes the type belongs, as specified in 4.5, “Operators and Expression Evaluation”. 9

**Discussion:** We no longer talk about the implicit declaration of basic operations. These are treated like an `if_statement` — they don't need to be declared, but are still applicable to only certain classes of types. 9.a

The *predefined types* [(for example the types `Boolean`, `Wide_Character`, `Integer`, *root integer*, and *universal integer*)] are the types that are defined in [a predefined library package called] `Standard`[; this package also includes the [(implicit)] declarations of their predefined operators]. [The package `Standard` is described in A.1.] 10

**Ramification:** We use the term “predefined” to refer to entities declared in the visible part of `Standard`, to implicitly declared operators of a type whose semantics are defined by the language, to `Standard` itself, and to the “predefined environment”. We do not use this term to refer to library packages other than `Standard`. For example `Text_IO` is a language-defined package, not a predefined package, and `Text_IO.Put_Line` is not a predefined operation. 10.a

#### Dynamic Semantics

The elaboration of a `full_type_declaration` consists of the elaboration of the full type definition. Each elaboration of a full type definition creates a distinct type and its first subtype. 11

**Reason:** The creation is associated with the type *definition*, rather than the type *declaration*, because there are types that are created by full type definitions that are not immediately contained within a type declaration (e.g. an array object declaration, a singleton task declaration, etc.). 11.a

**Ramification:** Any implicit declarations that occur immediately following the full type definition are elaborated where they (implicitly) occur. 11.b

#### Examples

*Examples of type definitions:* 12

```
(White, Red, Yellow, Green, Blue, Brown, Black) 13
range 1 .. 72
array(1 .. 10) of Integer
```

*Examples of type declarations:* 14

```
type Color is (White, Red, Yellow, Green, Blue, Brown, Black); 15
type Column is range 1 .. 72;
type Table is array(1 .. 10) of Integer;
```

#### NOTES

3 Each of the above examples declares a named type. The identifier given denotes the first subtype of the type. Other named subtypes of the type can be declared with `subtype_declarations` (see 3.2.2). Although names do not directly denote types, a phrase like “the type `Column`” is sometimes used in this International Standard to refer to the type of `Column`, where `Column` denotes the first subtype of the type. For an example of the definition of an anonymous type, see the declaration of the array `Color_Table` in 3.3.1; its type is anonymous — it has no nameable subtypes. 16

#### Wording Changes from Ada 83

The syntactic category `full_type_declaration` now includes task and protected type declarations. 16.a

{AI05-0299-1} We have generalized the concept of first-named subtype (now called simply “first subtype”) to cover all kinds of types, for uniformity of description elsewhere. RM83 defined first-named subtype in Section 13. We define 16.b/3

first subtype here, because it is now a more fundamental concept. We renamed the term, because in Ada 95 some first subtypes have no name.

- 16.c/2 {AI95-00230-01} We no longer elaborate `discriminant_parts`, because there is nothing to do, and it was complex to say that you only wanted to elaborate it once for a private or incomplete type. This is also consistent with the fact that subprogram specifications are not elaborated (neither in Ada 83 nor in Ada 95). Note, however, that an `access_definition` appearing in a `discriminant_part` is elaborated at the `full_type_declaration` (for a nonlimited type) or when an object with such a discriminant is created (for a limited type).

*Wording Changes from Ada 95*

- 16.d/2 {AI95-00230-01} Added wording so that anonymous access types are always full types, even if they appear in renames.
- 16.e/2 {AI95-00251-01} Added interface types (see 3.9.4) to the syntax.
- 16.f/2 {AI95-00326-01} Added a definition of full view, so that all types have a well-defined full view.

*Extensions to Ada 2005*

- 16.g/3 {AI05-0183-1} An optional `aspect_specification` can be used in a `full_type_declaration`. This is described in 13.1.1.

## 3.2.2 Subtype Declarations

- 1 A `subtype_declaration` declares a subtype of some previously declared type, as defined by a `subtype_indication`.

*Syntax*

- 2/3 {AI05-0183-1} `subtype_declaration ::=`  
**subtype** `defining_identifier is subtype_indication`  
`[aspect_specification];`
- 3/2 {AI95-00231-01} `subtype_indication ::= [null_exclusion] subtype_mark [constraint]`
- 4 `subtype_mark ::= subtype_name`
- 4.a **Ramification:** Note that name includes `attribute_reference`; thus, `S'Base` can be used as a `subtype_mark`.
- 4.b **Reason:** We considered changing `subtype_mark` to `subtype_name`. However, existing users are used to the word "mark," so we're keeping it.
- 5 `constraint ::= scalar_constraint | composite_constraint`
- 6 `scalar_constraint ::=`  
`range_constraint | digits_constraint | delta_constraint`
- 7 `composite_constraint ::=`  
`index_constraint | discriminant_constraint`

*Name Resolution Rules*

- 8 A `subtype_mark` shall resolve to denote a subtype. The type *determined by* a `subtype_mark` is the type of the subtype denoted by the `subtype_mark`.
- 8.a/3 **Ramification:** {AI05-0005-1} Types are never directly named; all `subtype_marks` denote subtypes — possibly an unconstrained (base) subtype, but never the type. When we use the term *anonymous type* we really mean a type with no nameable subtypes.

*Dynamic Semantics*

- 9 The elaboration of a `subtype_declaration` consists of the elaboration of the `subtype_indication`. The elaboration of a `subtype_indication` creates a new subtype. If the `subtype_indication` does not include a `constraint`, the new subtype has the same (possibly null) constraint as that denoted by the `subtype_mark`. The elaboration of a `subtype_indication` that includes a `constraint` proceeds as follows:
- 10 • The constraint is first elaborated.

- A check is then made that the constraint is *compatible* with the subtype denoted by the `subtype_mark`. 11

**Ramification:** The checks associated with constraint compatibility are all `Range_Checks`. `Discriminant_Checks` and `Index_Checks` are associated only with checks that a value satisfies a constraint. 11.a

The condition imposed by a constraint is the condition obtained after elaboration of the constraint. The rules defining compatibility are given for each form of constraint in the appropriate subclause. These rules are such that if a constraint is *compatible* with a subtype, then the condition imposed by the constraint cannot contradict any condition already imposed by the subtype on its values. The exception `Constraint_Error` is raised if any check of compatibility fails. 12

**To be honest:** The condition imposed by a constraint is named after it — a `range_constraint` imposes a range constraint, etc. 12.a

**Ramification:** A `range_constraint` causes freezing of its type. Other constraints do not. 12.b

#### NOTES

4 A `scalar_constraint` may be applied to a subtype of an appropriate scalar type (see 3.5, 3.5.9, and J.3), even if the subtype is already constrained. On the other hand, a `composite_constraint` may be applied to a composite subtype (or an access-to-composite subtype) only if the composite subtype is unconstrained (see 3.6.1 and 3.7.1). 13

#### Examples

*Examples of subtype declarations:* 14

```
{AI95-00433-01} subtype Rainbow is Color range Red .. Blue; -- see 3.2.1 15/2
subtype Red_Blue is Rainbow;
subtype Int is Integer;
subtype Small_Int is Integer range -10 .. 10;
subtype Up_To_K is Column range 1 .. K; -- see 3.2.1
subtype Square is Matrix(1 .. 10, 1 .. 10); -- see 3.6
subtype Male is Person(Sex => M); -- see 3.10.1
subtype Binop_Ref is not null Binop_Ptr; -- see 3.10
```

#### Incompatibilities With Ada 83

In Ada 95, all `range_constraints` cause freezing of their type. Hence, a type-related representation item for a scalar type has to precede any `range_constraints` whose type is the scalar type. 15.a

#### Wording Changes from Ada 83

`Subtype_marks` allow only subtype names now, since types are never directly named. There is no need for RM83-3.3.2(3), which says a `subtype_mark` can denote both the type and the subtype; in Ada 95, you denote an unconstrained (base) subtype if you want, but never the type. 15.b

The syntactic category `type_mark` is now called `subtype_mark`, since it always denotes a subtype. 15.c

#### Extensions to Ada 95

{AI95-00231-01} An optional `null_exclusion` can be used in a `subtype_indication`. This is described in 3.10. 15.d/2

#### Extensions to Ada 2005

{AI05-0183-1} An optional `aspect_specification` can be used in a `subtype_declaration`. This is described in 13.1.1. 15.e/3

## 3.2.3 Classification of Operations

#### Static Semantics

{AI95-00416-01} An operation *operates on a type*  $T$  if it yields a value of type  $T$ , if it has an operand whose expected type (see 8.6) is  $T$ , or if it has an access parameter or access result type (see 6.1) designating  $T$ . A predefined operator, or other language-defined operation such as assignment or a membership test, that operates on a type, is called a *predefined operation* of the type. The *primitive*

*operations* of a type are the predefined operations of the type, plus any user-defined primitive subprograms.

- 1.a **Glossary entry:** The primitive operations of a type are the operations (such as subprograms) declared together with the type declaration. They are inherited by other types in the same class of types. For a tagged type, the primitive subprograms are dispatching subprograms, providing run-time polymorphism. A dispatching subprogram may be called with statically tagged operands, in which case the subprogram body invoked is determined at compile time. Alternatively, a dispatching subprogram may be called using a dispatching call, in which case the subprogram body invoked is determined at run time.
- 1.b **To be honest:** Protected subprograms are not considered to be “primitive subprograms,” even though they are subprograms, and they are inherited by derived types.
- 1.c **Discussion:** We use the term “primitive subprogram” in most of the rest of the manual. The term “primitive operation” is used mostly in conceptual discussions.

2 The *primitive subprograms* of a specific type are defined as follows:

- 3 • The predefined operators of the type (see 4.5);
- 4 • For a derived type, the inherited (see 3.4) user-defined subprograms;
- 5 • For an enumeration type, the enumeration literals (which are considered parameterless functions — see 3.5.1);
- 6 • For a specific type declared immediately within a `package_specification`, any subprograms (in addition to the enumeration literals) that are explicitly declared immediately within the same `package_specification` and that operate on the type;
- 6.1/3 • *{AI05-0128-1}* For a specific type with an explicitly declared primitive "=" operator whose result type is Boolean, the corresponding "/=" operator (see 6.6);
- 7/2 • *{AI95-00200-01}* For a nonformal type, any subprograms not covered above [that are explicitly declared immediately within the same declarative region as the type] and that override (see 8.3) other implicitly declared primitive subprograms of the type.

- 7.a **Discussion:** In Ada 83, only subprograms declared in the visible part were “primitive” (i.e. derivable). In Ada 95, mostly because of child library units, we include all operations declared in the private part as well, and all operations that override implicit declarations.
- 7.b **Ramification:** It is possible for a subprogram to be primitive for more than one type, though it is illegal for a subprogram to be primitive for more than one tagged type. See 3.9.
- 7.c **Discussion:** The order of the implicit declarations when there are both predefined operators and inherited subprograms is described in 3.4, “Derived Types and Classes”.
- 7.d/2 **Ramification:** *{AI95-00200-01}* Subprograms declared in a generic package specification are never primitive for a formal type, even if they happen to override an operation of the formal type. This includes formal subprograms, which are never primitive operations (that's true even for an abstract formal subprogram).

8 A primitive subprogram whose designator is an `operator_symbol` is called a *primitive operator*.

#### *Incompatibilities With Ada 83*

- 8.a The attribute `S'Base` is no longer defined for nonscalar subtypes. Since this was only permitted as the prefix of another attribute, and there are no interesting nonscalar attributes defined for an unconstrained composite or access subtype, this should not affect any existing programs.

#### *Extensions to Ada 83*

- 8.b The primitive subprograms (derivable subprograms) include subprograms declared in the private part of a package specification as well, and those that override implicitly declared subprograms, even if declared in a body.

#### *Wording Changes from Ada 83*

- 8.c We have dropped the confusing term *operation of a type* in favor of the more useful *primitive operation of a type* and the phrase *operates on a type*.
- 8.d The description of `S'Base` has been moved to 3.5, “Scalar Types” because it is now defined only for scalar types.

*Wording Changes from Ada 95*

- {AI95-00200-01} Clarified that a formal subprogram that happens to override a primitive operation of a formal type is not a primitive operation (and thus not a dispatching operation) of the formal type. 8.e/2
- {AI95-00416-01} Added wording to include access result types in the kinds of operations that operate on a type T. 8.f/2

*Wording Changes from Ada 2005*

- {AI05-0128-1} **Correction:** The implicitly declared "`/=`" for a primitive "`=`" operator is also primitive; this makes it eligible to be made visible by a **use type** clause. 8.g/3

### 3.2.4 Subtype Predicates

{AI05-0153-3} {AI05-0269-1} {AI05-0299-1} The language-defined *predicate aspects* `Static_Predicate` and `Dynamic_Predicate` may be used to define properties of subtypes. A *predicate specification* is an `aspect_specification` for one of the two predicate aspects. General rules for aspects and `aspect_specifications` are found in Clause 13 (13.1 and 13.1.1 respectively). 1/3

**Aspect Description for `Static_Predicate`:** Condition that must hold true for objects of a given subtype; the subtype may be static. 1.a/3

**Aspect Description for `Dynamic_Predicate`:** Condition that must hold true for objects of a given subtype; the subtype is not static. 1.b/3

*Name Resolution Rules*

{AI05-0153-3} The expected type for a predicate aspect **expression** is any boolean type. 2/3

*Static Semantics*

{AI05-0153-3} A predicate specification may be given on a `type_declaration` or a `subtype_declaration`, and applies to the declared subtype. In addition, predicate specifications apply to certain other subtypes: 3/3

- For a (first) subtype defined by a derived type declaration, the predicates of the parent subtype and the progenitor subtypes apply. 4/3
- For a subtype created by a `subtype_indication`, the predicate of the subtype denoted by the `subtype_mark` applies. 5/3

{AI05-0153-3} The *predicate* of a subtype consists of all predicate specifications that apply, and-ed together; if no predicate specifications apply, the predicate is True [(in particular, the predicate of a base subtype is True)]. 6/3

{AI05-0290-1} Predicate checks are defined to be *enabled* or *disabled* for a given subtype as follows: 7/3

- If a subtype is declared by a `type_declaration` or `subtype_declaration` that includes a predicate specification, then: 8/3
  - if performing checks is required by the `Static_Predicate` assertion policy (see 11.4.2) and the declaration includes a `Static_Predicate` specification, then predicate checks are enabled for the subtype; 9/3
  - if performing checks is required by the `Dynamic_Predicate` assertion policy (see 11.4.2) and the declaration includes a `Dynamic_Predicate` specification, then predicate checks are enabled for the subtype; 10/3
  - otherwise, predicate checks are disabled for the subtype[, regardless of whether predicate checking is enabled for any other subtypes mentioned in the declaration]; 11/3
- If a subtype is defined by a derived type declaration that does not include a predicate specification, then predicate checks are enabled for the subtype if and only if predicate checks are enabled for at least one of the parent subtype and the progenitor subtypes; 12/3

- 13/3 • If a subtype is created by a `subtype_indication` other than in one of the previous cases, then predicate checks are enabled for the subtype if and only if predicate checks are enabled for the subtype denoted by the `subtype_mark`;
- 14/3 • Otherwise, predicate checks are disabled for the given subtype.
- 14.a/3 **Discussion:** In this case, no predicate specifications can apply to the subtype and so it doesn't typically matter whether predicate checks are enabled. This rule does make a difference, however, when determining whether predicate checks are enabled for another type when this type is one of multiple progenitors. See the “derived type declaration” wording above.
- 14.b/3 Even when predicate checks are disabled, a predicate can affect various Legality Rules, the results of membership tests, the items in a `for` loop, and the result of the `Valid` attribute.

*Legality Rules*

- 15/3 {*AI05-0153-3*} {*AI05-0269-1*} The expression of a `Static_Predicate` specification shall be *predicate-static*; that is, one of the following:
- 16/3 • a static expression;
- 17/3 • a membership test whose `simple_expression` is the current instance, and whose `membership_choice_list` meets the requirements for a static membership test (see 4.9);
- 18/3 • a `case_expression` whose `selecting_expression` is the current instance, and whose `dependent_expressions` are static expressions;
- 19/3 • a call to a predefined equality or ordering operator, where one operand is the current instance, and the other is a static expression;
- 20/3 • {*AI05-0262-1*} a call to a predefined boolean logical operator, where each operand is *predicate-static*;
- 21/3 • {*AI05-0269-1*} a short-circuit control form where both operands are *predicate-static*; or
- 22/3 • a parenthesized *predicate-static* expression.
- 23/3 {*AI05-0262-1*} A predicate shall not be specified for an incomplete subtype.
- 23.a/3 **Reason:** The expression of such a predicate could not depend on the properties of the value of the type (since it doesn't have any), so it is useless and we don't want to require the added complexity needed to support it.
- 24/3 {*AI05-0287-1*} If a predicate applies to a subtype, then that predicate shall not mention any other subtype to which the same predicate applies.
- 24.a/3 **Reason:** This is intended to prevent recursive predicates, which cause definitional problems for static predicates. Inside of the predicate, the subtype name refers to the current instance of the subtype, which is an object, so a direct use of the subtype name cannot be recursive. But other subtypes naming the same type might:
- 24.b/3
- ```

    type Really_Ugly is private;
  private
    subtype Ugly is Really_Ugly;
    type Really_Ugly is new Integer
      with Static_Predicate => Really_Ugly not in Ugly; -- Illegal!

```
- 25/3 {*AI05-0153-3*} An index subtype, `discrete_range` of an `index_constraint` or `slice`, or a `discrete_subtype_definition` of a `constrained_array_definition`, `entry_declaration`, or `entry_index_specification` shall not denote a subtype to which predicate specifications apply.
- 26/3 {*AI05-0153-3*} The prefix of an `attribute_reference` whose `attribute_designator` is `First`, `Last`, or `Range` shall not denote a scalar subtype to which predicate specifications apply.
- 26.a/3 **Reason:** {*AI05-0297-1*} This is to prevent confusion about whether the `First` value is the lowest value of the subtype (which does not depend on the predicate) or the lowest value of the subtype which meets the predicate. (For a dynamic predicate, determining this latter value is expensive as it would usually require a loop.) For a static subtype that has a static predicate, the `First_Valid` and `Last_Valid` attributes (see 3.5.5) can be used instead.

{AI05-0153-3} {AI05-0262-1} {AI05-0287-1} The `discrete_subtype_definition` of a `loop_parameter_specification` shall not denote a nonstatic subtype to which predicate specifications apply or any subtype to which `Dynamic_Predicate` specifications apply. 27/3

{AI05-0153-3} {AI05-0262-1} The `discrete_choice` of a `named_array_aggregate` shall not denote a nonstatic subtype to which predicate specifications apply. 28/3

Reason: {AI05-0262-1} This rule prevents noncontiguous dynamically bounded array aggregates, which could be expensive to check for. (Array aggregates have rules to prevent problems with static subtypes.) We define this rule here so that the runtime generic body check applies. 28.a/3

{AI05-0262-1} In addition to the places where Legality Rules normally apply (see 12.3), these rules apply also in the private part of an instance of a generic unit. 29/3

Dynamic Semantics

{AI05-0153-3} {AI05-0290-1} If predicate checks are enabled for a given subtype, then: 30/3

[On every subtype conversion, the predicate of the target subtype is evaluated, and a check is performed that the predicate is True. This includes all parameter passing, except for certain parameters passed by reference, which are covered by the following rule:] After normal completion and leaving of a subprogram, for each **in out** or **out** parameter that is passed by reference, the predicate of the subtype of the actual is evaluated, and a check is performed that the predicate is True. For an object created by an `object_declaration` with no explicit initialization expression, or by an uninitialized allocator, if any subcomponents have `default_expressions`, the predicate of the nominal subtype of the created object is evaluated, and a check is performed that the predicate is True. `Assertions.Assertion_Error` is raised if any of these checks fail. 31/3

Ramification: Predicates are not evaluated at the point of the (sub)type declaration. 31.a/3

Implementation Note: `Static_Predicate` checks can be removed even in the presence of potentially invalid values, just as constraint checks can be removed. 31.b/3

{AI05-0262-1} A value *satisfies* a predicate if the predicate is True for that value. 32/3

{AI05-0153-3} {AI05-0276-1} If any of the above Legality Rules is violated in an instance of a generic unit, `Program_Error` is raised at the point of the violation. 33/3

Discussion: This is the usual way around the contract model; this applies even in instance bodies. Note that errors in instance specifications will be detected at compile-time by the "re-check" of the specification, only errors in the body should raise `Program_Error`. 33.a/3

NOTES

5 {AI05-0153-3} A predicate specification does not cause a subtype to be considered constrained. 34/3

6 {AI05-0153-3} A `Static_Predicate`, like a constraint, always remains True for all objects of the subtype, except in the case of uninitialized variables and other invalid values. A `Dynamic_Predicate`, on the other hand, is checked as specified above, but can become False at other times. For example, the predicate of a record subtype is not checked when a subcomponent is modified. 35/3

Extensions to Ada 2005

{AI05-0153-3} {AI05-0262-1} {AI05-0276-1} {AI05-0290-1} Predicate aspects are new in Ada 2012. 35.a/3

3.3 Objects and Named Numbers

[Objects are created at run time and contain a value of a given type. An object can be created and initialized as part of elaborating a declaration, evaluating an `allocator`, `aggregate`, or `function_call`, or passing a parameter by copy. Prior to reclaiming the storage for an object, it is finalized if necessary (see 7.6.1).] 1

2 All of the following are objects:

2.a **Glossary entry:** An object is either a constant or a variable. An object contains a value. An object is created by an `object_declaration` or by an allocator. A formal parameter is (a view of) an object. A subcomponent of an object is an object.

- 3 • the entity declared by an `object_declaration`;
- 4 • a formal parameter of a subprogram, entry, or generic subprogram;
- 5 • a generic formal object;
- 6 • a loop parameter;
- 7 • a choice parameter of an `exception_handler`;
- 8 • an entry index of an `entry_body`;
- 9 • the result of dereferencing an access-to-object value (see 4.1);
- 10/3 • $\{AI95-00416-01\}$ $\{AI05-0015-1\}$ the return object of a function;
- 11 • the result of evaluating an aggregate;
- 11.1/3 • $\{AI05-0003-1\}$ a `qualified_expression` whose operand denotes an object;
- 12 • a component, slice, or view conversion of another object.

13/3 $\{AI05-0054-2\}$ An object is either a *constant* object or a *variable* object. Similarly, a view of an object is either a *constant* or a *variable*. All views of a constant elementary object are constant. All views of a constant composite object are constant, except for parts that are of controlled or immutably limited types; variable views of those parts and their subcomponents may exist. In this sense, objects of controlled and immutably limited types are *inherently mutable*. A constant view of an object cannot be used to modify its value. The terms constant and variable by themselves refer to constant and variable views of objects.

14 The value of an object is *read* when the value of any part of the object is evaluated, or when the value of an enclosing object is evaluated. The value of a variable is *updated* when an assignment is performed to any part of the variable, or when an assignment is performed to an enclosing object.

14.a **Ramification:** Reading and updating are intended to include read/write references of any kind, even if they are not associated with the evaluation of a particular construct. Consider, for example, the expression “`X.all(F)`”, where X is an access-to-array object, and F is a function. The implementation is allowed to first evaluate “`X.all`” and then F. Finally, a read is performed to get the value of the F'th component of the array. Note that the array is not necessarily read as part of the evaluation of “`X.all`”. This is important, because if F were to free X using `Unchecked_Deallocation`, we want the execution of the final read to be erroneous.

15 Whether a view of an object is constant or variable is determined by the definition of the view. The following (and no others) represent constants:

- 16 • an object declared by an `object_declaration` with the reserved word **constant**;
- 16.a/2 **To be honest:** $\{AI95-00385-01\}$ We mean the word **constant** as defined by the grammar for `object_declaration`, not some random word **constant**. Thus,
 - 16.b/2 `X : access constant T;`
 - 16.c/2 is not a constant.
- 17 • a formal parameter or generic formal object of mode **in**;
- 18 • a discriminant;
- 18.1/3 • $\{AI05-0262-1\}$ a loop parameter unless specified to be a variable for a generalized loop (see 5.5.2);
- 19/3 • $\{AI05-0262-1\}$ a choice parameter or entry index;
- 20 • the dereference of an access-to-constant value;

- {AI05-0015-1} the return object declared by an `extended_return_statement` with the reserved word **constant**; 20.1/3
 - {AI05-0015-1} the object denoted by a `function_call` or an aggregate; 21/3
 - {AI05-0003-1} the result of evaluating a `qualified_expression`; 21.1/3
 - {AI05-0120-1} within the body of a protected function (or a function declared immediately within a `protected_body`), the current instance of the enclosing protected unit; 21.2/3
 - a `selected_component`, `indexed_component`, `slice`, or view conversion of a constant. 22
- {AI05-0264-1} At the place where a view of an object is defined, a *nominal subtype* is associated with the view. The object's *actual subtype* (that is, its subtype) can be more restrictive than the nominal subtype of the view; it always is if the nominal subtype is an *indefinite subtype*. A subtype is an indefinite subtype if it is an unconstrained array subtype, or if it has unknown discriminants or unconstrained discriminants without defaults (see 3.7); otherwise, the subtype is a *definite subtype* [(all elementary subtypes are definite subtypes)]. [A class-wide subtype is defined to have unknown discriminants, and is therefore an indefinite subtype. An indefinite subtype does not by itself provide enough information to create an object; an additional constraint or explicit initialization expression is necessary (see 3.3.1). A component cannot have an indefinite nominal subtype.] 23/3
- {AI05-0008-1} A view of a composite object is *known to be constrained* if: 23.1/3
- its nominal subtype is constrained, and is not an untagged partial view; or 23.2/3
 - its nominal subtype is indefinite; or 23.3/3
 - {AI05-0008-1} {AI05-0093-1} its type is immutably limited (see 7.5); or 23.4/3
 - it is part of a stand-alone constant (including a generic formal object of mode **in**); or 23.5/3
 - it is part of a formal parameter of mode **in**; or 23.6/3
 - it is part of the object denoted by a `function_call` or aggregate; or 23.7/3
 - it is part of a constant return object of an `extended_return_statement`; or 23.8/3
 - {AI05-0008-1} {AI05-0041-1} it is a dereference of a pool-specific access type, and there is no ancestor of its type that has a constrained partial view. 23.9/3
- Discussion:** We do not include dereferences of general access types because they might denote stand-alone aliased unconstrained variables. That's true even for access-to-constant types (the denoted object does not have to be a constant). 23.a/3
- {AI05-0005-1} {AI05-0008-1} There are other cases that could have been included in this definition (view conversions, the current instance of a type, objects of a formal discriminated private type), but these are not relevant to the places this term is used, so they were not included. If this term is used in additional places, the definition should be checked to see if any of these additional cases are relevant and appropriate wording added if necessary. 23.b/3
- {AI05-0008-1} {AI05-0041-1} For the purposes of determining within a generic body whether an object is known to be constrained: 23.10/3
- if a subtype is a descendant of an untagged generic formal private or derived type, and the subtype is not an unconstrained array subtype, it is not considered indefinite and is considered to have a constrained partial view; 23.11/3
 - if a subtype is a descendant of a formal access type, it is not considered pool-specific. 23.12/3
- A *named number* provides a name for a numeric value known at compile time. It is declared by a `number_declaration`. 24

NOTES

- 7 A constant cannot be the target of an assignment operation, nor be passed as an **in out** or **out** parameter, between its initialization and finalization, if any. 25

- 25.1/3 8 {AI05-0054-2} The value of a constant object cannot be changed after its initialization, except in some cases where the object has a controlled or immutably limited part (see 7.5, 7.6, and 13.9.1).
- 26/3 9 {AI05-0264-1} The nominal and actual subtypes of an elementary object are always the same. For a discriminated or array object, if the nominal subtype is constrained, then so is the actual subtype.

Extensions to Ada 83

- 26.a There are additional kinds of objects (choice parameters and entry indices of entry bodies).
- 26.b The result of a function and of evaluating an aggregate are considered (constant) objects. This is necessary to explain the action of finalization on such things. Because a `function_call` is also syntactically a `name` (see 4.1), the result of a `function_call` can be renamed, thereby allowing repeated use of the result without calling the function again.

Wording Changes from Ada 83

- 26.c/3 {AI05-0299-1} This subclause now follows the subclauses on types and subtypes, to cut down on the number of forward references.
- 26.d The term nominal subtype is new. It is used to distinguish what is known at compile time about an object's constraint, versus what its "true" run-time constraint is.
- 26.e The terms definite and indefinite (which apply to subtypes) are new. They are used to aid in the description of generic formal type matching, and to specify when an explicit initial value is required in an `object_declaration`.
- 26.f We have moved the syntax for `object_declaration` and `number_declaration` down into their respective subclauses, to keep the syntax close to the description of the associated semantics.
- 26.g We talk about variables and constants here, since the discussion is not specific to `object_declarations`, and it seems better to have the list of the kinds of constants juxtaposed with the kinds of objects.
- 26.h We no longer talk about indirect updating due to parameter passing. Parameter passing is handled in 6.2 and 6.4.1 in a way that there is no need to mention it here in the definition of read and update. Reading and updating now includes the case of evaluating or assigning to an enclosing object.

Wording Changes from Ada 95

- 26.i/2 {AI95-00416-01} Clarified that the return object is the object created by a function call.

Extensions to Ada 2005

- 26.j/3 {AI05-0015-1} Added wording to allow return objects to be declared as constants, and corrected the definition of return objects as objects.

Wording Changes from Ada 2005

- 26.k/3 {AI05-0008-1} {AI05-0041-1} {AI05-0093-1} **Correction:** Added a definition of *known to be constrained*, for use in other rules.
- 26.l/3 {AI05-0054-2} **Correction:** We now recognize the fact that not all declared constant objects are immutable; for those that a variable view can be constructed, they can be changed via that view.
- 26.m/3 {AI05-0120-1} **Correction:** Added the current instance of a protected object to the list of constant views; since the list claims to include all possibilities, it had better include that one.
- 26.n/3 {AI05-0003-1} The result of a `qualified_expression` is defined to be a constant view and is defined to be an object if the operand of the `qualified_expression` is an object. These definitions, combined with some grammar changes, allow `qualified_expressions` to be used in more places. See 4.1 for details.

3.3.1 Object Declarations

- 1/3 {AI05-0262-1} An `object_declaration` declares a *stand-alone* object with a given nominal subtype and, optionally, an explicit initial value given by an initialization expression. For an array, access, task, or protected object, the `object_declaration` may include the definition of the (anonymous) type of the object.

Syntax

{AI95-00385-01} *{AI95-00406-01}* *{AI05-0183-1}* `object_declaration ::=` 2/3
`defining_identifier_list : [aliased] [constant] subtype_indication [:= expression]`
`[aspect_specification];`
`| defining_identifier_list : [aliased] [constant] access_definition [:= expression]`
`[aspect_specification];`
`| defining_identifier_list : [aliased] [constant] array_type_definition [:= expression]`
`[aspect_specification];`
`| single_task_declaration`
`| single_protected_declaration`
`defining_identifier_list ::=` 3
`defining_identifier {, defining_identifier}`

Name Resolution Rules

For an `object_declaration` with an `expression` following the compound delimiter `:=`, the type expected for the `expression` is that of the object. This `expression` is called the *initialization expression*. 4

Legality Rules

{AI95-00287-01} An `object_declaration` without the reserved word **constant** declares a variable object. If it has a `subtype_indication` or an `array_type_definition` that defines an indefinite subtype, then there shall be an initialization expression. 5/2

Static Semantics

{AI05-0264-1} *{AI05-0299-1}* An `object_declaration` with the reserved word **constant** declares a constant object. If it has an initialization expression, then it is called a *full constant declaration*. Otherwise, it is called a *deferred constant declaration*. The rules for deferred constant declarations are given in subclause 7.4. The rules for full constant declarations are given in this subclause. 6/3

Any declaration that includes a `defining_identifier_list` with more than one `defining_identifier` is equivalent to a series of declarations each containing one `defining_identifier` from the list, with the rest of the text of the declaration copied for each declaration in the series, in the same order as the list. The remainder of this International Standard relies on this equivalence; explanations are given for declarations with a single `defining_identifier`. 7

{AI95-00385-01} The `subtype_indication`, `access_definition`, or full type definition of an `object_declaration` defines the nominal subtype of the object. The `object_declaration` declares an object of the type of the nominal subtype. 8/2

Discussion: *{AI95-00385-01}* The phrase “full type definition” here includes the case of an anonymous array, access, task, or protected type. 8.a/2

{AI95-00373-01} A component of an object is said to *require late initialization* if it has an access discriminant value constrained by a per-object expression, or if it has an initialization expression that includes a name denoting the current instance of the type or denoting an access discriminant. 8.1/2

Reason: Such components can depend on the values of other components of the object. We want to initialize them as late and as reproducibly as possible. 8.b/2

Dynamic Semantics

{AI95-00363-01} If a composite object declared by an `object_declaration` has an unconstrained nominal subtype, then if this subtype is indefinite or the object is constant the actual subtype of this object is constrained. The constraint is determined by the bounds or discriminants (if any) of its initial value; the object is said to be *constrained by its initial value*. When not constrained by its initial value, the actual 9/2

and nominal subtypes of the object are the same. If its actual subtype is constrained, the object is called a *constrained object*.

- 10 For an `object_declaration` without an initialization expression, any initial values for the object or its subcomponents are determined by the *implicit initial values* defined for its nominal subtype, as follows:
- 11 • The implicit initial value for an access subtype is the null value of the access type.
 - 11.1/3 • *{AI05-0228-1}* The implicit initial value for a scalar subtype that has the `Default_Value` aspect specified is the value of that aspect converted to the nominal subtype (which might raise `Constraint_Error` — see 4.6, “Type Conversions”);
 - 11.a.1/3 **Ramification:** This is a Dynamic Semantics rule, so the visibility of the `aspect_specification` is not relevant — if the full type for a private type has the `Default_Value` aspect specified, partial views of the type also have this implicit initial value.
 - 12 • The implicit initial (and only) value for each discriminant of a constrained discriminated subtype is defined by the subtype.
 - 13/3 • *{AI05-0228-1}* For a (definite) composite subtype, the implicit initial value of each component with a `default_expression` is obtained by evaluation of this expression and conversion to the component's nominal subtype (which might raise `Constraint_Error`), unless the component is a discriminant of a constrained subtype (the previous case), or is in an excluded `variant` (see 3.8.1). For each component that does not have a `default_expression`, if the composite subtype has the `Default_Component_Value` aspect specified, the implicit initial value is the value of that aspect converted to the component's nominal subtype; otherwise, any implicit initial values are those determined by the component's nominal subtype.
 - 14 • For a protected or task subtype, there is an implicit component (an entry queue) corresponding to each entry, with its implicit initial value being an empty queue.
 - 14.a **Implementation Note:** The implementation may add implicit components for its own use, which might have implicit initial values. For a task subtype, such components might represent the state of the associated thread of control. For a type with dynamic-sized components, such implicit components might be used to hold the offset to some explicit component.
- 15 The elaboration of an `object_declaration` proceeds in the following sequence of steps:
- 16/2 1. *{AI95-00385-01}* The `subtype_indication`, `access_definition`, `array_type_definition`, `single_task_declaration`, or `single_protected_declaration` is first elaborated. This creates the nominal subtype (and the anonymous type in the last four cases).
 - 17 2. If the `object_declaration` includes an initialization expression, the (explicit) initial value is obtained by evaluating the expression and converting it to the nominal subtype (which might raise `Constraint_Error` — see 4.6).
 - 18/2 3. *{8652/0002}* *{AI95-00171-01}* *{AI95-00373-01}* The object is created, and, if there is not an initialization expression, the object is *initialized by default*. When an object is initialized by default, any per-object constraints (see 3.8) are elaborated and any implicit initial values for the object or for its subcomponents are obtained as determined by the nominal subtype. Any initial values (whether explicit or implicit) are assigned to the object or to the corresponding subcomponents. As described in 5.2 and 7.6, `Initialize` and `Adjust` procedures can be called.
 - 18.a **Discussion:** For a per-object constraint that contains some per-object expressions and some non-per-object expressions, the values used for the constraint consist of the values of the non-per-object expressions evaluated at the point of the `type_declaration`, and the values of the per-object expressions evaluated at the point of the creation of the object.
 - 18.b The elaboration of per-object constraints was presumably performed as part of the dependent compatibility check in Ada 83. If the object is of a limited type with an access discriminant, the `access_definition` is elaborated at this time (see 3.7).
 - 18.c **Reason:** The reason we say that evaluating an explicit initialization expression happens before creating the object is that in some cases it is impossible to know the size of the object being created until its initial value is known, as in “X:

- String := Func_Call(...);". The implementation can create the object early in the common case where the size can be known early, since this optimization is semantically neutral.
- This paragraph was deleted. {AI95-00373-01}* 19/2
- Ramification:** Since the initial values have already been converted to the appropriate nominal subtype, the only Constraint_Errors that might occur as part of these assignments are for values outside their base range that are used to initialize unconstrained numeric subcomponents. See 3.5. 19.a
- {AI95-00373-01} For the third step above, evaluations and assignments are performed in an arbitrary order subject to the following restrictions: 20/2
- {AI95-00373-01} Assignment to any part of the object is preceded by the evaluation of the value that is to be assigned. 20.1/2

Reason: Duh. But we ought to say it. Note that, like any rule in the International Standard, it doesn't prevent an "as-if" optimization; as long as the semantics as observed from the program are correct, the compiler can generate any code it wants. 20.a.1/2
 - {AI95-00373-01} The evaluation of a default_expression that includes the name of a discriminant is preceded by the assignment to that discriminant. 20.2/2

Reason: Duh again. But we have to say this, too. It's odd that Ada 95 only required the default expressions to be evaluated before the discriminant is used; it says nothing about discriminant values that come from subtype_indications. 20.a.2/2
 - {AI95-00373-01} The evaluation of the default_expression for any component that depends on a discriminant is preceded by the assignment to that discriminant. 20.3/2

Reason: For example: 20.a

```

type R(D : Integer := F) is
  record
    S : String(1..D) := (others => G);
  end record;
X : R;

```

20.b

For the elaboration of the declaration of X, it is important that F be evaluated before the aggregate. 20.c

20.d
 - {AI95-00373-01} {AI05-0092-1} The assignments to any components, including implicit components, not requiring late initialization precede the initial value evaluations for any components requiring late initialization; if two components both require late initialization, then assignments to parts of the component occurring earlier in the order of the component declarations precede the initial value evaluations of the component occurring later. 20.4/3

Reason: Components that require late initialization can refer to the entire object during their initialization. We want them to be initialized as late as possible to reduce the chance that their initialization depends on uninitialized components. For instance: 20.e/2

```

type T (D : Natural) is
  limited record
    C1 : T1 (T'Access);
    C2 : Natural := F (D);
    C3 : String (1 .. D) := (others => ' ');
  end record;

```

20.f/2

Component C1 requires late initialization. The initialization could depend on the values of any component of T, including D, C2, or C3. Therefore, we want it to be initialized last. Note that C2 and C3 do not require late initialization; they only have to be initialized after D. 20.g/2

It is possible for there to be more than one component that requires late initialization. In this case, the language can't prevent problems, because all of the components can't be the last one initialized. In this case, we specify the order of initialization for components requiring late initialization; by doing so, programmers can arrange their code to avoid accessing uninitialized components, and such arrangements are portable. Note that if the program accesses an uninitialized component, 13.9.1 defines the execution to be erroneous. 20.h/2
- {AI05-0228-1} [There is no implicit initial value defined for a scalar subtype unless the Default_Value aspect has been specified for the type.] In the absence of an explicit initialization or the specification of the Default_Value aspect, a newly created scalar object might have a value that does not belong to its subtype (see 13.9.1 and H.1). 21/3

- 21.a **To be honest:** It could even be represented by a bit pattern that doesn't actually represent any value of the type at all, such as an invalid internal code for an enumeration type, or a NaN for a floating point type. It is generally a bounded error to reference scalar objects with such “invalid representations”, as explained in 13.9.1, “Data Validity”.
- 21.b **Ramification:** There is no requirement that two objects of the same scalar subtype have the same implicit initial “value” (or representation). It might even be the case that two elaborations of the same `object_declaration` produce two different initial values. However, any particular uninitialized object is default-initialized to a single value (or invalid representation). Thus, multiple reads of such an uninitialized object will produce the same value each time (if the implementation chooses not to detect the error).

NOTES

- 22 10 Implicit initial values are not defined for an indefinite subtype, because if an object's nominal subtype is indefinite, an explicit initial value is required.
- 23/3 11 *{AI05-0092-1}* *{AI05-0255-1}* As indicated above, a stand-alone object is an object declared by an `object_declaration`. Similar definitions apply to “stand-alone constant” and “stand-alone variable.” A subcomponent of an object is not a stand-alone object, nor is an object that is created by an allocator. An object declared by a `loop_parameter_specification`, `iterator_specification`, `parameter_specification`, `entry_index_specification`, `choice_parameter_specification`, `extended_return_statement`, or a formal `object_declaration` of mode `in out` is not considered a stand-alone object.
- 24 12 The type of a stand-alone object cannot be abstract (see 3.9.3).

Examples

- 25 *Example of a multiple object declaration:*
- 26 *-- the multiple object declaration*
- 27/2 *{AI95-00433-01}* John, Paul : **not null** Person_Name := **new** Person(Sex => M); *-- see 3.10.1*
- 28 *-- is equivalent to the two single object declarations in the order given*
- 29/2 *{AI95-00433-01}* John : **not null** Person_Name := **new** Person(Sex => M);
Paul : **not null** Person_Name := **new** Person(Sex => M);

30 *Examples of variable declarations:*

- 31/2 *{AI95-00433-01}* Count, Sum : Integer;
Size : Integer **range** 0 .. 10_000 := 0;
Sorted : Boolean := False;
Color_Table : **array**(1 .. Max) **of** Color;
Option : Bit_Vector(1 .. 10) := (**others** => True);
Hello : **aliased** String := "Hi, world.";
 θ , ϕ : Float **range** $-\pi$.. $+\pi$;

32 *Examples of constant declarations:*

- 33/2 *{AI95-00433-01}* Limit : **constant** Integer := 10_000;
Low_Limit : **constant** Integer := Limit/10;
Tolerance : **constant** Real := Dispersion(1.15);
Hello_Msg : **constant access** String := Hello'Access; *-- see 3.10.2*

Extensions to Ada 83

- 33.a The syntax rule for `object_declaration` is modified to allow the **aliased** reserved word.
- 33.b A variable declared by an `object_declaration` can be constrained by its initial value; that is, a variable of a nominally unconstrained array subtype, or discriminated type without defaults, can be declared so long as it has an explicit initial value. In Ada 83, this was permitted for constants, and for variables created by allocators, but not for variables declared by `object_declarations`. This is particularly important for tagged class-wide types, since there is no way to constrain them explicitly, and so an initial value is the only way to provide a constraint. It is also important for generic formal private types with unknown discriminants.
- 33.c We now allow an `unconstrained_array_definition` in an `object_declaration`. This allows an object of an anonymous array type to have its bounds determined by its initial value. This is for uniformity: If one can write “X: **constant array**(Integer **range** 1..10) **of** Integer := ...;” then it makes sense to also allow “X: **constant array**(Integer **range** \diamond) **of** Integer := ...;”. (Note that if anonymous array types are ever sensible, a common situation is for a table implemented as an array. Tables are often constant, and for constants, there's usually no point in forcing the user to count the number of elements in the value.)

Wording Changes from Ada 83

- We have moved the syntax for `object_declarations` into this subclause. 33.d
- Deferred constants no longer have a separate syntax rule, but rather are incorporated in `object_declaration` as constants declared without an initialization expression. 33.e

Inconsistencies With Ada 95

- {AI95-00363-01} Unconstrained aliased objects of types with discriminants with defaults are no longer constrained by their initial values. This means that a program that raised `Constraint_Error` from an attempt to change the discriminants will no longer do so. The change only affects programs that depended on the raising of `Constraint_Error` in this case, so the inconsistency is unlikely to occur outside of the ACATS. This change may however cause compilers to implement these objects differently, possibly taking additional memory or time. This is unlikely to be worse than the differences caused by any major compiler upgrade. 33.f/2

Extensions to Ada 95

- {AI95-00287-01} A constant may have a limited type; the initialization expression has to be built-in-place (see 7.5). 33.g/2
- {AI95-00385-01} {AI95-00406-01} A stand-alone object may have an anonymous access type. 33.h/2

Wording Changes from Ada 95

- {8652/0002} {AI95-00171-01} **Corrigendum:** Corrected wording to say that per-object constraints are elaborated (not evaluated). 33.i/2
- {AI95-00373-01} The rules for evaluating default initialization have been tightened. In particular, components whose default initialization can refer to the rest of the object are required to be initialized last. 33.j/2
- {AI95-00433-01} Added examples of various new constructs. 33.k/2

Extensions to Ada 2005

- {AI05-0183-1} An optional `aspect_specification` can be used in an `object_declaration`. This is described in 13.1.1. 33.l/3

Wording Changes from Ada 2005

- {AI05-0228-1} Implicit initial values can now be given for scalar types and for scalar array components, using the `Default_Value` (see 3.5) and `Default_Component_Value` (see 3.6) aspects; the extension is documented there. 33.m/3

3.3.2 Number Declarations

- A `number_declaration` declares a named number. 1
- Discussion:** {AI05-0299-1} If a value or other property of a construct is required to be *static* that means it is required to be determined prior to execution. A *static* expression is an expression whose value is computed at compile time and is usable in contexts where the actual value might affect the legality of the construct. This is fully defined in subclause 4.9. 1.a/3

Syntax

```
number_declaration ::=
  defining_identifier_list : constant := static_expression; 2
```

Name Resolution Rules

- The *static_expression* given for a `number_declaration` is expected to be of any numeric type. 3

Legality Rules

- {AI05-0299-1} The *static_expression* given for a number declaration shall be a static expression, as defined by subclause 4.9. 4/3

Static Semantics

- 5 The named number denotes a value of type *universal_integer* if the type of the *static_expression* is an integer type. The named number denotes a value of type *universal_real* if the type of the *static_expression* is a real type.
- 6 The value denoted by the named number is the value of the *static_expression*, converted to the corresponding universal type.

Dynamic Semantics

- 7 The elaboration of a *number_declaration* has no effect.
- 7.a **Proof:** Since the *static_expression* was evaluated at compile time.

Examples

8 *Examples of number declarations:*

```

9     Two_Pi          : constant := 2.0*Ada.Numerics.Pi;    -- a real number (see A.5)
10/2  {AI95-00433-01} Max          : constant := 500;      -- an integer number
     Max_Line_Size  : constant := Max/6;                -- the integer 83
     Power_16       : constant := 2**16;                -- the integer 65_536
     One, Un, Eins  : constant := 1;                    -- three different names for 1

```

Extensions to Ada 83

- 10.a We now allow a static expression of any numeric type to initialize a named number. For integer types, it was possible in Ada 83 to use 'Pos to define a named number, but there was no way to use a static expression of some nonuniversal real type to define a named number. This change is upward compatible because of the preference rule for the operators of the root numeric types.

Wording Changes from Ada 83

- 10.b We have moved the syntax rule into this subclause.
- 10.c AI83-00263 describes the elaboration of a number declaration in words similar to that of an *object_declaration*. However, since there is no expression to be evaluated and no object to be created, it seems simpler to say that the elaboration has no effect.

3.4 Derived Types and Classes

- 1/2 {AI95-00401-01} {AI95-00419-01} A *derived_type_definition* defines a *derived type* (and its first subtype) whose characteristics are *derived* from those of a parent type, and possibly from progenitor types.
- 1.a/2 **Glossary entry:** A derived type is a type defined in terms of one or more other types given in a derived type definition. The first of those types is the parent type of the derived type and any others are progenitor types. Each class containing the parent type or a progenitor type also contains the derived type. The derived type inherits properties such as components and primitive operations from the parent and progenitors. A type together with the types derived from it (directly or indirectly) form a derivation class.
- 1.1/2 {AI95-00442-01} A *class of types* is a set of types that is closed under derivation; that is, if the parent or a progenitor type of a derived type belongs to a class, then so does the derived type. By saying that a particular group of types forms a class, we are saying that all derivatives of a type in the set inherit the characteristics that define that set. The more general term *category of types* is used for a set of types whose defining characteristics are not necessarily inherited by derivatives; for example, limited, abstract, and interface are all categories of types, but not classes of types.
- 1.b/2 **Ramification:** A class of types is also a category of types.

Syntax

{AI95-00251-01} {AI95-00419-01} `derived_type_definition ::=` 2/2
[abstract] [limited] new *parent_subtype_indication* **[and** *interface_list* **] record_extension_part**

Legality Rules

{AI95-00251-01} {AI95-00401-01} {AI95-00419-01} The *parent_subtype_indication* defines the *parent subtype*; its type is the *parent type*. The *interface_list* defines the progenitor types (see 3.9.4). A derived type has one parent type and zero or more progenitor types. 3/2

Glossary entry: The parent of a derived type is the first type given in the definition of the derived type. The parent can be almost any kind of type, including an interface type. 3.a/2

A type shall be completely defined (see 3.11.1) prior to being specified as the parent type in a `derived_type_definition` — [the `full_type_declarations` for the parent type and any of its subcomponents have to precede the `derived_type_definition`.] 4

Discussion: This restriction does not apply to the ancestor type of a private extension — see 7.3; such a type need not be completely defined prior to the `private_extension_declaration`. However, the restriction does apply to record extensions, so the ancestor type will have to be completely defined prior to the `full_type_declaration` corresponding to the `private_extension_declaration`. 4.a

Reason: We originally hoped we could relax this restriction. However, we found it too complex to specify the rules for a type derived from an incompletely defined limited type that subsequently became nonlimited. 4.b

{AI95-00401-01} If there is a `record_extension_part`, the derived type is called a *record extension* of the parent type. A `record_extension_part` shall be provided if and only if the parent type is a tagged type. [An `interface_list` shall be provided only if the parent type is a tagged type.] 5/2

Proof: {AI95-00401-01} The syntax only allows an `interface_list` to appear with a `record_extension_part`, and a `record_extension_part` can only be provided if the parent type is a tagged type. We give the last sentence anyway for completeness. 5.a.1/2

Implementation Note: We allow a record extension to inherit discriminants; an early version of Ada 9X did not. If the parent subtype is unconstrained, it can be implemented as though its discriminants were repeated in a new `known_discriminant_part` and then used to constrain the old ones one-for-one. However, in an extension aggregate, the discriminants in this case do not appear in the component association list. 5.a

Ramification: {AI95-00114-01} This rule needs to be rechecked in the visible part of an instance of a generic unit because of the “only if” part of the rule. For example: 5.b/2

```
generic
  type T is private;
  package P is
    type Der is new T;
  end P;
package I is new P (Some_Tagged_Type); -- illegal
```

5.c/2

5.d/2

{AI95-00114-01} The instantiation is illegal because a tagged type is being extended in the visible part without a `record_extension_part`. Note that this is legal in the private part or body of an instance, both to avoid a contract model violation, and because no code that can see that the type is actually tagged can also see the derived type declaration. 5.e/2

No recheck is needed for derived types with a `record_extension_part`, as that has to be derived from something that is known to be tagged (otherwise the template is illegal). 5.f/2

{AI95-00419-01} {AI05-0096-1} If the reserved word **limited** appears in a `derived_type_definition`, the parent type shall be a limited type. If the parent type is a tagged formal type, then in addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit. 5.1/3

Reason: We allow **limited** because we don't inherit limitedness from interfaces, so we must have a way to derive a limited type from interfaces. The word **limited** has to be legal when the parent *could be* an interface, and that includes generic formal abstract types. Since we have to allow it in this case, we might as well allow it everywhere as documentation, to make it explicit that the type is limited. 5.g/2

However, we do not want to allow **limited** when the parent is nonlimited: limitedness cannot change in a derivation tree. 5.h/2

- 5.i/3 If the parent type is an untagged limited formal type with an actual type that is nonlimited, we allow derivation as a limited type in the private part or body as no place could have visibility on the resulting type where it was known to be nonlimited (outside of the instance). (See the previous paragraph's annotations for an explanation of this.) However, if the parent type is a tagged limited formal type with an actual type that is nonlimited, it would be possible to pass a value of the limited type extension to a class-wide type of the parent, which would be nonlimited. That's too weird to allow (even though all of the extension components would have to be nonlimited because the rules of 3.9.1 are rechecked), so we have a special rule to prevent that in the private part (type extension from a formal type is illegal in a generic package body).

Static Semantics

- 6 The first subtype of the derived type is unconstrained if a `known_discriminant_part` is provided in the declaration of the derived type, or if the parent subtype is unconstrained. Otherwise, the constraint of the first subtype *corresponds* to that of the parent subtype in the following sense: it is the same as that of the parent subtype except that for a range constraint (implicit or explicit), the value of each bound of its range is replaced by the corresponding value of the derived type.
- 6.a **Discussion:** A `digits_constraint` in a `subtype_indication` for a decimal fixed point subtype always imposes a range constraint, implicitly if there is no explicit one given. See 3.5.9, “Fixed Point Types”.
- 6.1/2 `{AI95-00231-01}` The first subtype of the derived type excludes null (see 3.10) if and only if the parent subtype excludes null.
- 7/3 `{AI05-0110-1}` The *characteristics* and implicitly declared primitive subprograms of the derived type are defined as follows:
- 7.a/3 **Ramification:** `{AI05-0110-1}` The characteristics of a type do not include its primitive subprograms (primitive subprograms include predefined operators). The rules governing availability/visibility and inheritance of characteristics are separate from those for primitive subprograms.
- 8/2 • `{AI95-00251-01}` `{AI95-00401-01}` `{AI95-00442-01}` [If the parent type or a progenitor type belongs to a class of types, then the derived type also belongs to that class.] The following sets of types, as well as any higher-level sets composed from them, are classes in this sense[, and hence the characteristics defining these classes are inherited by derived types from their parent or progenitor types]: signed integer, modular integer, ordinary fixed, decimal fixed, floating point, enumeration, boolean, character, access-to-constant, general access-to-variable, pool-specific access-to-variable, access-to-subprogram, array, string, non-array composite, nonlimited, untagged record, tagged, task, protected, and synchronized tagged.
- 8.a **Discussion:** This is inherent in our notion of a “class” of types. It is not mentioned in the initial definition of “class” since at that point type derivation has not been defined. In any case, this rule ensures that every class of types is closed under derivation.
- 9 • If the parent type is an elementary type or an array type, then the set of possible values of the derived type is a copy of the set of possible values of the parent type. For a scalar type, the base range of the derived type is the same as that of the parent type.
- 9.a **Discussion:** The base range of a type defined by an `integer_type_definition` or a `real_type_definition` is determined by the `_definition`, and is not necessarily the same as that of the corresponding root numeric type from which the newly defined type is implicitly derived. Treating numerics types as implicitly derived from one of the two root numeric types is simply to link them into a type hierarchy; such an implicit derivation does not follow all the rules given here for an explicit `derived_type_definition`.
- 10 • If the parent type is a composite type other than an array type, then the components, protected subprograms, and entries that are declared for the derived type are as follows:
- 11 • The discriminants specified by a new `known_discriminant_part`, if there is one; otherwise, each discriminant of the parent type (implicitly declared in the same order with the same specifications) — in the latter case, the discriminants are said to be *inherited*, or if unknown in the parent, are also unknown in the derived type;

- Each nondiscriminant component, entry, and protected subprogram of the parent type, implicitly declared in the same order with the same declarations; these components, entries, and protected subprograms are said to be *inherited*; 12
 - Ramification:** The profiles of entries and protected subprograms do not change upon type derivation, although the type of the “implicit” parameter identified by the prefix of the name in a call does. 12.a
 - To be honest:** Any name in the parent `type_declaration` that denotes the current instance of the type is replaced with a name denoting the current instance of the derived type, converted to the parent type. 12.b
 - Each component declared in a `record_extension_part`, if any. 13
- Declarations of components, protected subprograms, and entries, whether implicit or explicit, occur immediately within the declarative region of the type, in the order indicated above, following the parent `subtype_indication`. 14
- Discussion:** The order of declarations within the region matters for `record_aggregates` and `extension_aggregates`. 14.a
 - Ramification:** In most cases, these things are implicitly declared *immediately* following the parent `subtype_indication`. However, 7.3.1, “Private Operations” defines some cases in which they are implicitly declared later, and some cases in which they are not declared at all. 14.b
 - Discussion:** The place of the implicit declarations of inherited components matters for visibility — they are not visible in the `known_discriminant_part` nor in the parent `subtype_indication`, but are usually visible within the `record_extension_part`, if any (although there are restrictions on their use). Note that a discriminant specified in a new `known_discriminant_part` is not considered “inherited” even if it has the same name and subtype as a discriminant of the parent type. 14.c
- *This paragraph was deleted.* {AI95-00419-01} 15/2
 - [For each predefined operator of the parent type, there is a corresponding predefined operator of the derived type.] 16
 - Proof:** This is a ramification of the fact that each class that includes the parent type also includes the derived type, and the fact that the set of predefined operators that is defined for a type, as described in 4.5, is determined by the classes to which it belongs. 16.a
 - Reason:** Predefined operators are handled separately because they follow a slightly different rule than user-defined primitive subprograms. In particular the systematic replacement described below does not apply fully to the relational operators for Boolean and the exponentiation operator for Integer. The relational operators for a type derived from Boolean still return Standard.Boolean. The exponentiation operator for a type derived from Integer still expects Standard.Integer for the right operand. In addition, predefined operators “reemerge” when a type is the actual type corresponding to a generic formal type, so they need to be well defined even if hidden by user-defined primitive subprograms. 16.b
 - {AI95-00401-01} For each user-defined primitive subprogram (other than a user-defined equality operator — see below) of the parent type or of a progenitor type that already exists at the place of the `derived_type_definition`, there exists a corresponding *inherited* primitive subprogram of the derived type with the same defining name. Primitive user-defined equality operators of the parent type and any progenitor types are also inherited by the derived type, except when the derived type is a nonlimited record extension, and the inherited operator would have a profile that is type conformant with the profile of the corresponding predefined equality operator; in this case, the user-defined equality operator is not inherited, but is rather incorporated into the implementation of the predefined equality operator of the record extension (see 4.5.2). 17/2
 - Ramification:** We say “...already exists...” rather than “is visible” or “has been declared” because there are certain operations that are declared later, but still exist at the place of the `derived_type_definition`, and there are operations that are never declared, but still exist. These cases are explained in 7.3.1. 17.a
 - Note that nonprivate extensions can appear only after the last primitive subprogram of the parent — the freezing rules ensure this. 17.b
 - Reason:** A special case is made for the equality operators on nonlimited record extensions because their predefined equality operators are already defined in terms of the primitive equality operator of their parent type (and of the tagged components of the extension part). Inheriting the parent's equality operator as is would be undesirable, because it would ignore any components of the extension part. On the other hand, if the parent type is limited, then any user-defined equality operator is inherited as is, since there is no predefined equality operator to take its place. 17.c

- 17.d/2 **Ramification:** *{AI95-00114-01}* Because user-defined equality operators are not inherited by nonlimited record extensions, the formal parameter names of = and /= revert to Left and Right, even if different formal parameter names were used in the user-defined equality operators of the parent type.
- 17.e/2 **Discussion:** *{AI95-00401-01}* This rule only describes what operations are inherited; the rules that describe what happens when there are conflicting inherited subprograms are found in 8.3.
- 18/3 *{AI95-00401-01}* *{AI05-0164-1}* *{AI05-0240-1}* The profile of an inherited subprogram (including an inherited enumeration literal) is obtained from the profile of the corresponding (user-defined) primitive subprogram of the parent or progenitor type, after systematic replacement of each subtype of its profile (see 6.1) that is of the parent or progenitor type, other than those subtypes found in the designated profile of an `access_definition`, with a *corresponding subtype* of the derived type. For a given subtype of the parent or progenitor type, the corresponding subtype of the derived type is defined as follows:
- 19 • If the declaration of the derived type has neither a `known_discriminant_part` nor a `record_extension_part`, then the corresponding subtype has a constraint that corresponds (as defined above for the first subtype of the derived type) to that of the given subtype.
 - 20 • If the derived type is a record extension, then the corresponding subtype is the first subtype of the derived type.
 - 21 • If the derived type has a new `known_discriminant_part` but is not a record extension, then the corresponding subtype is constrained to those values that when converted to the parent type belong to the given subtype (see 4.6).
- 21.a **Reason:** An inherited subprogram of an untagged type has an Intrinsic calling convention, which precludes the use of the Access attribute. We preclude 'Access because correctly performing all required constraint checks on an indirect call to such an inherited subprogram was felt to impose an undesirable implementation burden.
- 21.b/3 *{AI05-0164-1}* Note that the exception to substitution of the parent or progenitor type applies only in the profiles of anonymous access-to-subprogram types. The exception is necessary to avoid calling an access-to-subprogram with types and/or constraints different than expected by the actual routine.
- 22/2 *{AI95-00401-01}* The same formal parameters have `default_expressions` in the profile of the inherited subprogram. [Any type mismatch due to the systematic replacement of the parent or progenitor type by the derived type is handled as part of the normal type conversion associated with parameter passing — see 6.4.1.]
- 22.a/2 **Reason:** *{AI95-00401-01}* We don't introduce the type conversion explicitly here since conversions to record extensions or on access parameters are not generally legal. Furthermore, any type conversion would just be "undone" since the subprogram of the parent or progenitor is ultimately being called anyway. (Null procedures can be inherited from a progenitor without being overridden, so it is possible to call subprograms of an interface.)
- 23/2 *{AI95-00401-01}* If a primitive subprogram of the parent or progenitor type is visible at the place of the `derived_type_definition`, then the corresponding inherited subprogram is implicitly declared immediately after the `derived_type_definition`. Otherwise, the inherited subprogram is implicitly declared later or not at all, as explained in 7.3.1.
- 24 A derived type can also be defined by a `private_extension_declaration` (see 7.3) or a `formal_derived_type_definition` (see 12.5.1). Such a derived type is a partial view of the corresponding full or actual type.
- 25 All numeric types are derived types, in that they are implicitly derived from a corresponding root numeric type (see 3.5.4 and 3.5.6).

Dynamic Semantics

- 26 The elaboration of a `derived_type_definition` creates the derived type and its first subtype, and consists of the elaboration of the `subtype_indication` and the `record_extension_part`, if any. If the `subtype_indication` depends on a discriminant, then only those expressions that do not depend on a discriminant are evaluated.

- Discussion:** {AI95-00251-01} We don't mention the `interface_list`, because it does not need elaboration (see 3.9.4). This is consistent with the handling of `discriminant_parts`, which aren't elaborated either. 26.a/2
- {AI95-00391-01} {AI95-00401-01} For the execution of a call on an inherited subprogram, a call on the corresponding primitive subprogram of the parent or progenitor type is performed; the normal conversion of each actual parameter to the subtype of the corresponding formal parameter (see 6.4.1) performs any necessary type conversion as well. If the result type of the inherited subprogram is the derived type, the result of calling the subprogram of the parent or progenitor is converted to the derived type, or in the case of a null extension, extended to the derived type using the equivalent of an `extension_aggregate` with the original result as the `ancestor_part` and **null record** as the `record_component_association_list`. 27/2
- Discussion:** {AI95-00391-01} If an inherited function returns the derived type, and the type is a nonnull record extension, then the inherited function shall be overridden, unless the type is abstract (in which case the function is abstract, and (unless overridden) cannot be called except via a dispatching call). See 3.9.3. 27.a/2
- NOTES
- 13 Classes are closed under derivation — any class that contains a type also contains its derivatives. Operations available for a given class of types are available for the derived types in that class. 28
- 14 Evaluating an inherited enumeration literal is equivalent to evaluating the corresponding enumeration literal of the parent type, and then converting the result to the derived type. This follows from their equivalence to parameterless functions. 29
- 15 A generic subprogram is not a subprogram, and hence cannot be a primitive subprogram and cannot be inherited by a derived type. On the other hand, an instance of a generic subprogram can be a primitive subprogram, and hence can be inherited. 30
- 16 If the parent type is an access type, then the parent and the derived type share the same storage pool; there is a **null** access value for the derived type and it is the implicit initial value for the type. See 3.10. 31
- 17 If the parent type is a boolean type, the predefined relational operators of the derived type deliver a result of the predefined type Boolean (see 4.5.2). If the parent type is an integer type, the right operand of the predefined exponentiation operator is of the predefined type Integer (see 4.5.6). 32
- 18 Any discriminants of the parent type are either all inherited, or completely replaced with a new set of discriminants. 33
- 19 For an inherited subprogram, the subtype of a formal parameter of the derived type need not have any value in common with the first subtype of the derived type. 34
- Proof:** This happens when the parent subtype is constrained to a range that does not overlap with the range of a subtype of the parent type that appears in the profile of some primitive subprogram of the parent type. For example: 34.a
- ```

type T1 is range 1..100;
subtype S1 is T1 range 1..10;
procedure P(X : in S1); -- P is a primitive subprogram
type T2 is new T1 range 11..20;
-- implicitly declared:
-- procedure P(X : in T2'Base range 1..10);
-- X cannot be in T2'First .. T2'Last

```
- 34.b
- 20 If the reserved word **abstract** is given in the declaration of a type, the type is abstract (see 3.9.3). 35
- 21 {AI95-00251-01} {AI95-00401-01} An interface type that has a progenitor type “is derived from” that type. A `derived_type_definition`, however, never defines an interface type. 35.1/2
- 22 {AI95-00345-01} It is illegal for the parent type of a `derived_type_definition` to be a synchronized tagged type. 35.2/2
- Proof:** {AI05-0299-1} 3.9.1 prohibits record extensions whose parent type is a synchronized tagged type, and this subclause requires tagged types to have a record extension. Thus there are no legal derivations. Note that a synchronized interface can be used as a progenitor in an `interface_type_definition` as well as in task and protected types, but we do not allow concrete extensions of any synchronized tagged type. 35.a/3

#### Examples

*Examples of derived type declarations:*

```

type Local_Coordinate is new Coordinate; -- two different types
type Midweek is new Day range Tue .. Thu; -- see 3.5.1
type Counter is new Positive; -- same range as Positive

```

38 `type Special_Key is new Key_Manager.Key; -- see 7.3.1`  
 -- the inherited subprograms have the following specifications:  
 -- procedure Get\_Key(K : out Special\_Key);  
 -- function "<(X,Y : Special\_Key) return Boolean;

*Inconsistencies With Ada 83*

38.a When deriving from a (nonprivate, nonderived) type in the same visible part in which it is defined, if a predefined operator had been overridden prior to the derivation, the derived type will inherit the user-defined operator rather than the predefined operator. The work-around (if the new behavior is not the desired behavior) is to move the definition of the derived type prior to the overriding of any predefined operators.

*Incompatibilities With Ada 83*

38.b When deriving from a (nonprivate, nonderived) type in the same visible part in which it is defined, a primitive subprogram of the parent type declared before the derived type will be inherited by the derived type. This can cause upward incompatibilities in cases like this:

```
38.c package P is
 type T is (A, B, C, D);
 function F(X : T := A) return Integer;
 type NT is new T;
 -- inherits F as
 -- function F(X : NT := A) return Integer;
 -- in Ada 95 only
 ...
end P;
...
use P; -- Only one declaration of F from P is use-visible in
 -- Ada 83; two declarations of F are use-visible in
 -- Ada 95.
begin
 ...
 if F > 1 then ... -- legal in Ada 83, ambiguous in Ada 95
```

*Extensions to Ada 83*

38.d The syntax for a `derived_type_definition` is amended to include an optional `record_extension_part` (see 3.9.1).

38.e A derived type may override the discriminants of the parent by giving a new `discriminant_part`.

38.f The parent type in a `derived_type_definition` may be a derived type defined in the same visible part.

38.g When deriving from a type in the same visible part in which it is defined, the primitive subprograms declared prior to the derivation are inherited as primitive subprograms of the derived type. See 3.2.3.

*Wording Changes from Ada 83*

38.h We now talk about the classes to which a type belongs, rather than a single class.

*Extensions to Ada 95*

38.i/2 *{AI05-0190-1}* *{AI95-00251-01}* *{AI95-00401-01}* A derived type may inherit from multiple (interface) progenitors, as well as the parent type — see 3.9.4, “Interface Types”.

38.j/2 *{AI95-00419-01}* A derived type may specify that it is a limited type. This is required for interface ancestors (from which limitedness is not inherited), but it is generally useful as documentation of limitedness.

*Wording Changes from Ada 95*

38.k/2 *{AI95-00391-01}* Defined the result of functions for null extensions (which we no longer require to be overridden - see 3.9.3).

38.l/2 *{AI95-00442-01}* Defined the term “category of types” and used it in wording elsewhere; also specified the language-defined categories that form classes of types (this was never normatively specified in Ada 95).

*Incompatibilities With Ada 2005*

38.m/3 *{AI05-0096-1}* **Correction:** Added a (re)check that limited type extensions never are derived from nonlimited types in generic private parts. This is disallowed as it would make it possible to pass a limited object to a nonlimited class-wide type, which could then be copied. This is only possible using Ada 2005 syntax, so examples in existing programs should be rare.

## Wording Changes from Ada 2005

{AI05-0110-1} **Correction:** Added wording to clarify that the characteristics of derived types are formally defined here. (This is the only place in the Standard that actually spells out what sorts of things are actually characteristics, which is rather important.) 38.n/3

{AI05-0164-1} **Correction:** Added wording to ensure that anonymous access-to-subprogram types don't get modified on derivation. 38.o/3

### 3.4.1 Derivation Classes

In addition to the various language-defined classes of types, types can be grouped into *derivation classes*. 1

#### Static Semantics

{AI95-00251-01} {AI95-00401-01} A derived type is *derived from* its parent type *directly*; it is derived *indirectly* from any type from which its parent type is derived. A derived type, interface type, type extension, task type, protected type, or formal derived type is also derived from every ancestor of each of its progenitor types, if any. The derivation class of types for a type *T* (also called the class *rooted* at *T*) is the set consisting of *T* (the *root type* of the class) and all types derived from *T* (directly or indirectly) plus any associated universal or class-wide types (defined below). 2/2

**Discussion:** Note that the definition of “derived from” is a recursive definition. We don't define a root type for all interesting language-defined classes, though presumably we could. 2.a

**To be honest:** By the class-wide type “associated” with a type *T*, we mean the type *T*Class. Similarly, the universal type associated with *root\_integer*, *root\_real*, and *root\_fixed* are *universal\_integer*, *universal\_real*, and *universal\_fixed*, respectively. 2.b

{AI95-00230-01} Every type is either a *specific* type, a *class-wide* type, or a *universal* type. A specific type is one defined by a *type\_declaration*, a *formal\_type\_declaration*, or a full type definition embedded in another construct. Class-wide and universal types are implicitly defined, to act as representatives for an entire class of types, as follows: 3/2

**To be honest:** The root types *root\_integer*, *root\_real*, and *root\_fixed* are also specific types. They are declared in the specification of package Standard. 3.a

Class-wide types 4

Class-wide types are defined for [(and belong to)] each derivation class rooted at a tagged type (see 3.9). Given a subtype *S* of a tagged type *T*, *S*'Class is the *subtype\_mark* for a corresponding subtype of the tagged class-wide type *T*Class. Such types are called “class-wide” because when a formal parameter is defined to be of a class-wide type *T*Class, an actual parameter of any type in the derivation class rooted at *T* is acceptable (see 8.6).

The set of values for a class-wide type *T*Class is the discriminated union of the set of values of each specific type in the derivation class rooted at *T* (the tag acts as the implicit discriminant — see 3.9). Class-wide types have no primitive subprograms of their own. However, as explained in 3.9.2, operands of a class-wide type *T*Class can be used as part of a dispatching call on a primitive subprogram of the type *T*. The only components [(including discriminants)] of *T*Class that are visible are those of *T*. If *S* is a first subtype, then *S*'Class is a first subtype. 5

**Reason:** We want *S*'Class to be a first subtype when *S* is, so that an *attribute\_definition\_clause* like “**for** *S*'Class'Output **use** ...;” will be legal. 5.a

{AI95-00230-01} Universal types 6/2

Universal types are defined for [(and belong to)] the integer, real, fixed point, and access classes, and are referred to in this standard as respectively, *universal\_integer*, *universal\_real*, *universal\_fixed*, and *universal\_access*. These are analogous to class-wide types for these language-defined elementary classes. As with class-wide types, if a formal parameter is of a universal type, then an actual parameter of any type in the corresponding class is acceptable.

In addition, a value of a universal type (including an integer or real `numeric_literal`, or the literal `null`) is “universal” in that it is acceptable where some particular type in the class is expected (see 8.6).

- 7 The set of values of a universal type is the undiscriminated union of the set of values possible for any definable type in the associated class. Like class-wide types, universal types have no primitive subprograms of their own. However, their “universality” allows them to be used as operands with the primitive subprograms of any type in the corresponding class.
- 7.a **Discussion:** A class-wide type is only class-wide in one direction, from specific to class-wide, whereas a universal type is class-wide (universal) in both directions, from specific to universal and back.
- 7.b/2 {AI95-00230-01} We considered defining class-wide or perhaps universal types for all derivation classes, not just tagged classes and these four elementary classes. However, this was felt to overly weaken the strong-typing model in some situations. Tagged types preserve strong type distinctions thanks to the run-time tag. Class-wide or universal types for untagged types would weaken the compile-time type distinctions without providing a compensating run-time-checkable distinction.
- 7.c We considered defining standard names for the universal numeric types so they could be used in formal parameter specifications. However, this was felt to impose an undue implementation burden for some implementations.
- 7.d **To be honest:** Formally, the set of values of a universal type is actually a *copy* of the undiscriminated union of the values of the types in its class. This is because we want each value to have exactly one type, with explicit or implicit conversion needed to go between types. An alternative, consistent model would be to associate a class, rather than a particular type, with a value, even though any given expression would have a particular type. In that case, implicit type conversions would not generally need to change the value, although an associated subtype conversion might need to.
- 8 The integer and real numeric classes each have a specific root type in addition to their universal type, named respectively *root\_integer* and *root\_real*.
- 9 A class-wide or universal type is said to *cover* all of the types in its class. A specific type covers only itself.
- 10/2 {AI95-00230-01} {AI95-00251-01} A specific type *T2* is defined to be a *descendant* of a type *T1* if *T2* is the same as *T1*, or if *T2* is derived (directly or indirectly) from *T1*. A class-wide type *T2*'Class is defined to be a descendant of type *T1* if *T2* is a descendant of *T1*. Similarly, the numeric universal types are defined to be descendants of the root types of their classes. If a type *T2* is a descendant of a type *T1*, then *T1* is called an *ancestor* of *T2*. An *ultimate ancestor* of a type is an ancestor of that type that is not itself a descendant of any other type. Every untagged type has a unique ultimate ancestor.
- 10.a **Ramification:** A specific type is a descendant of itself. Class-wide types are considered descendants of the corresponding specific type, and do not have any descendants of their own.
- 10.b A specific type is an ancestor of itself. The root of a derivation class is an ancestor of all types in the class, including any class-wide types in the class.
- 10.c **Discussion:** The terms root, parent, ancestor, and ultimate ancestor are all related. For example:
- 10.d/2
- {AI95-00251-01} Each type has at most one parent, and one or more ancestor types; each untagged type has exactly one ultimate ancestor. In Ada 83, the term “parent type” was sometimes used more generally to include any ancestor type (e.g. RM83-9.4(14)). In Ada 95, we restrict parent to mean the immediate ancestor.
- 10.e
- A class of types has at most one root type; a derivation class has exactly one root type.
- 10.f
- The root of a class is an ancestor of all of the types in the class (including itself).
- 10.g
- The type *root\_integer* is the root of the integer class, and is the ultimate ancestor of all integer types. A similar statement applies to *root\_real*.
- 10.h/2 **Glossary entry:** An ancestor of a type is the type itself or, in the case of a type derived from other types, its parent type or one of its progenitor types or one of their ancestors. Note that ancestor and descendant are inverse relationships.
- 10.i/2 **Glossary entry:** A type is a descendant of itself, its parent and progenitor types, and their ancestors. Note that descendant and ancestor are inverse relationships.
- 11 An inherited component [(including an inherited discriminant)] of a derived type is inherited *from* a given ancestor of the type if the corresponding component was inherited by each derived type in the chain of derivations going back to the given ancestor.

## NOTES

23 Because operands of a universal type are acceptable to the predefined operators of any type in their class, ambiguity can result. For *universal\_integer* and *universal\_real*, this potential ambiguity is resolved by giving a preference (see 8.6) to the predefined operators of the corresponding root types (*root\_integer* and *root\_real*, respectively). Hence, in an apparently ambiguous expression like

$1 + 4 < 7$  13

where each of the literals is of type *universal\_integer*, the predefined operators of *root\_integer* will be preferred over those of other specific integer types, thereby resolving the ambiguity. 14

**Ramification:** Except for this preference, a root numeric type is essentially like any other specific type in the associated numeric class. In particular, the result of a predefined operator of a root numeric type is not “universal” (implicitly convertible) even if both operands were. 14.a

*Wording Changes from Ada 95*

{AI95-00230-01} Updated the wording to define the *universal\_access* type. This was defined to make **null** for anonymous access types sensible. 14.b/2

{AI95-00251-01} {AI95-00401-01} The definitions of ancestors and descendants were updated to allow multiple ancestors (necessary to support interfaces). 14.c/2

### 3.5 Scalar Types

*Scalar* types comprise enumeration types, integer types, and real types. Enumeration types and integer types are called *discrete* types; each value of a discrete type has a *position number* which is an integer value. Integer types and real types are called *numeric* types. [All scalar types are ordered, that is, all relational operators are predefined for their values.] 1

*Syntax*

`range_constraint ::= range range` 2

`range ::= range_attribute_reference  
| simple_expression .. simple_expression` 3

**Discussion:** These need to be *simple\_expressions* rather than more general *expressions* because ranges appear in membership tests and other contexts where *expression .. expression* would be ambiguous. 3.a

A *range* has a *lower bound* and an *upper bound* and specifies a subset of the values of some scalar type (the *type of the range*). A range with lower bound L and upper bound R is described by “L .. R”. If R is less than L, then the range is a *null range*, and specifies an empty set of values. Otherwise, the range specifies the values of the type from the lower bound to the upper bound, inclusive. A value *belongs* to a range if it is of the type of the range, and is in the subset of values specified by the range. A value *satisfies* a range constraint if it belongs to the associated range. One range is *included* in another if all values that belong to the first range also belong to the second. 4

*Name Resolution Rules*

For a *subtype\_indication* containing a *range\_constraint*, either directly or as part of some other *scalar\_constraint*, the type of the range shall resolve to that of the type determined by the *subtype\_mark* of the *subtype\_indication*. For a range of a given type, the *simple\_expressions* of the range (likewise, the *simple\_expressions* of the equivalent range for a *range\_attribute\_reference*) are expected to be of the type of the range. 5

**Discussion:** In Ada 95, constraints only appear within *subtype\_indications*; things that look like constraints that appear in type declarations are called something else like *real\_range\_specifications*. 5.a

{AI05-0299-1} We say “the expected type is ...” or “the type is expected to be ...” depending on which reads better. They are fundamentally equivalent, and both feed into the type resolution rules of subclause 8.6. 5.b/3

In some cases, it doesn’t work to use expected types. For example, in the above rule, we say that the “type of the range shall resolve to ...” rather than “the expected type for the range is ...”. We then use “expected type” for the bounds. If 5.c

we used “expected” at both points, there would be an ambiguity, since one could apply the rules of 8.6 either on determining the type of the range, or on determining the types of the individual bounds. It is clearly important to allow one bound to be of a universal type, and the other of a specific type, so we need to use “expected type” for the bounds. Hence, we used “shall resolve to” for the type of the range as a whole. There are other situations where “expected type” is not quite right, and we use “shall resolve to” instead.

*Static Semantics*

- 6 The *base range* of a scalar type is the range of finite values of the type that can be represented in every unconstrained object of the type; it is also the range supported at a minimum for intermediate values during the evaluation of expressions involving predefined operators of the type.
- 6.a **Implementation Note:** Note that in some machine architectures intermediates in an expression (particularly if static), and register-resident variables might accommodate a wider range. The base range does not include the values of this wider range that are not assignable without overflow to memory-resident objects.
- 6.b **Ramification:** The base range of an enumeration type is the range of values of the enumeration type.
- 6.c **Reason:** If the representation supports infinities, the base range is nevertheless restricted to include only the representable finite values, so that 'Base'First and 'Base'Last are always guaranteed to be finite.
- 6.d **To be honest:** By a "value that can be assigned without overflow" we don't mean to restrict ourselves to values that can be represented exactly. Values between machine representable values can be assigned, but on subsequent reading, a slightly different value might be retrieved, as (partially) determined by the number of digits of precision of the type.
- 7 [A constrained scalar subtype is one to which a range constraint applies.] The *range* of a constrained scalar subtype is the range associated with the range constraint of the subtype. The *range* of an unconstrained scalar subtype is the base range of its type.

*Dynamic Semantics*

- 8 A range is *compatible* with a scalar subtype if and only if it is either a null range or each bound of the range belongs to the range of the subtype. A *range\_constraint* is *compatible* with a scalar subtype if and only if its range is compatible with the subtype.
- 8.a **Ramification:** Only *range\_constraints* (explicit or implicit) impose conditions on the values of a scalar subtype. The other *scalar\_constraints*, *digits\_constraints* and *delta\_constraints* impose conditions on the subtype denoted by the *subtype\_mark* in a *subtype\_indication*, but don't impose a condition on the values of the subtype being defined. Therefore, a scalar subtype is not called *constrained* if all that applies to it is a *digits\_constraint*. Decimal subtypes are subtle, because a *digits\_constraint* without a *range\_constraint* nevertheless includes an implicit *range\_constraint*.
- 9 The elaboration of a *range\_constraint* consists of the evaluation of the *range*. The evaluation of a *range* determines a lower bound and an upper bound. If *simple\_expressions* are given to specify bounds, the evaluation of the *range* evaluates these *simple\_expressions* in an arbitrary order, and converts them to the type of the range. If a *range\_attribute\_reference* is given, the evaluation of the *range* consists of the evaluation of the *range\_attribute\_reference*.

10 *Attributes*

- 11 For every scalar subtype S, the following attributes are defined:
- 12 S'First      S'First denotes the lower bound of the range of S. The value of this attribute is of the type of S.
- 12.a **Ramification:** Evaluating S'First never raises Constraint\_Error.
- 13 S'Last      S'Last denotes the upper bound of the range of S. The value of this attribute is of the type of S.
- 13.a **Ramification:** Evaluating S'Last never raises Constraint\_Error.
- 14 S'Range      S'Range is equivalent to the range S'First .. S'Last.
- 15 S'Base      S'Base denotes an unconstrained subtype of the type of S. This unconstrained subtype is called the *base subtype* of the type.

|                   |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |        |

| S'Min             | S'Min denotes a function with the following specification:                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 | 16     |
|                   | <pre>function S'Min(<i>Left</i>, <i>Right</i> : S'Base)   return S'Base</pre>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              | 17     |
|                   | The function returns the lesser of the values of the two parameters.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       | 18     |
|                   | <b>Discussion:</b> The formal parameter names are italicized because they cannot be used in calls — see 6.4. Such a specification cannot be written by the user because an <code>attribute_reference</code> is not permitted as the designator of a user-defined function, nor can its formal parameters be anonymous.                                                                                                                                                                                                                                                                                                                                     | 18.a   |
| S'Max             | S'Max denotes a function with the following specification:                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 | 19     |
|                   | <pre>function S'Max(<i>Left</i>, <i>Right</i> : S'Base)   return S'Base</pre>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              | 20     |
|                   | The function returns the greater of the values of the two parameters.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      | 21     |
| S'Succ            | S'Succ denotes a function with the following specification:                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                | 22     |
|                   | <pre>function S'Succ(<i>Arg</i> : S'Base)   return S'Base</pre>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            | 23     |
|                   | For an enumeration type, the function returns the value whose position number is one more than that of the value of <i>Arg</i> ; <code>Constraint_Error</code> is raised if there is no such value of the type. For an integer type, the function returns the result of adding one to the value of <i>Arg</i> . For a fixed point type, the function returns the result of adding <i>small</i> to the value of <i>Arg</i> . For a floating point type, the function returns the machine number (as defined in 3.5.7) immediately above the value of <i>Arg</i> ; <code>Constraint_Error</code> is raised if there is no such machine number.               | 24     |
|                   | <b>Ramification:</b> S'Succ for a modular integer subtype wraps around if the value of <i>Arg</i> is S'Base'Last. S'Succ for a signed integer subtype might raise <code>Constraint_Error</code> if the value of <i>Arg</i> is S'Base'Last, or it might return the out-of-base-range value S'Base'Last+1, as is permitted for all predefined numeric operations.                                                                                                                                                                                                                                                                                            | 24.a   |
| S'Pred            | S'Pred denotes a function with the following specification:                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                | 25     |
|                   | <pre>function S'Pred(<i>Arg</i> : S'Base)   return S'Base</pre>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            | 26     |
|                   | For an enumeration type, the function returns the value whose position number is one less than that of the value of <i>Arg</i> ; <code>Constraint_Error</code> is raised if there is no such value of the type. For an integer type, the function returns the result of subtracting one from the value of <i>Arg</i> . For a fixed point type, the function returns the result of subtracting <i>small</i> from the value of <i>Arg</i> . For a floating point type, the function returns the machine number (as defined in 3.5.7) immediately below the value of <i>Arg</i> ; <code>Constraint_Error</code> is raised if there is no such machine number. | 27     |
|                   | <b>Ramification:</b> S'Pred for a modular integer subtype wraps around if the value of <i>Arg</i> is S'Base'First. S'Pred for a signed integer subtype might raise <code>Constraint_Error</code> if the value of <i>Arg</i> is S'Base'First, or it might return the out-of-base-range value S'Base'First-1, as is permitted for all predefined numeric operations.                                                                                                                                                                                                                                                                                         | 27.a   |
| S'Wide_Wide_Image | S'Wide_Wide_Image denotes a function with the following specification:                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     | 27.1/2 |
|                   | <pre>{AI95-00285-01} function S'Wide_Wide_Image(<i>Arg</i> : S'Base)   return Wide_Wide_String</pre>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       | 27.2/2 |
|                   | The function returns an <i>image</i> of the value of <i>Arg</i> , that is, a sequence of characters representing the value in display form. The lower bound of the result is one.                                                                                                                                                                                                                                                                                                                                                                                                                                                                          | 27.3/2 |
|                   | The image of an integer value is the corresponding decimal literal, without underlines, leading zeros, exponent, or trailing spaces, but with a single leading character that is either a minus sign or a space.                                                                                                                                                                                                                                                                                                                                                                                                                                           | 27.4/2 |
|                   | <b>Implementation Note:</b> If the machine supports negative zeros for signed integer types, it is not specified whether "0" or "-0" should be returned for negative zero. We don't have enough experience with such machines to know what is appropriate, and what other languages do. In any case, the implementation should be consistent.                                                                                                                                                                                                                                                                                                              | 27.b/2 |

- 27.5/2 The image of an enumeration value is either the corresponding identifier in upper case or the corresponding character literal (including the two apostrophes); neither leading nor trailing spaces are included. For a *nongraphic character* (a value of a character type that has no enumeration literal associated with it), the result is a corresponding language-defined name in upper case (for example, the image of the nongraphic character identified as *nul* is “NUL” — the quotes are not part of the image).
- 27.c/2 **Implementation Note:** For an enumeration type *T* that has “holes” (caused by an *enumeration\_representation\_-clause*), *T**Wide\_Image* should raise *Program\_Error* if the value is one of the holes (which is a bounded error anyway, since holes can be generated only via uninitialized variables and similar things).
- 27.6/2 The image of a floating point value is a decimal real literal best approximating the value (rounded away from zero if halfway between) with a single leading character that is either a minus sign or a space, a single digit (that is nonzero unless the value is zero), a decimal point, *S**Digits*−1 (see 3.5.8) digits after the decimal point (but one if *S**Digits* is one), an upper case *E*, the sign of the exponent (either + or −), and two or more digits (with leading zeros if necessary) representing the exponent. If *S**Signed\_Zeros* is *True*, then the leading character is a minus sign for a negatively signed zero.
- 27.d/2 **To be honest:** Leading zeros are present in the exponent only if necessary to make the exponent at least two digits.
- 27.e/2 **Reason:** This image is intended to conform to that produced by *Text\_IO.Float\_IO.Put* in its default format.
- 27.f/2 **Implementation Note:** The rounding direction is specified here to ensure portability of output results.
- 27.7/2 The image of a fixed point value is a decimal real literal best approximating the value (rounded away from zero if halfway between) with a single leading character that is either a minus sign or a space, one or more digits before the decimal point (with no redundant leading zeros), a decimal point, and *S**Aft* (see 3.5.10) digits after the decimal point.
- 27.g/2 **Reason:** This image is intended to conform to that produced by *Text\_IO.Fixed\_IO.Put*.
- 27.h/2 **Implementation Note:** The rounding direction is specified here to ensure portability of output results.
- 27.i/2 **Implementation Note:** For a machine that supports negative zeros, it is not specified whether “0.000” or “−0.000” is returned. See corresponding comment above about integer types with signed zeros.
- 28 *S**Wide\_Image* *S**Wide\_Image* denotes a function with the following specification:
- 29       **function** *S**Wide\_Image* (*Arg* : *S**Base*)  
          **return** *Wide\_String*
- 30/3       {*AI95-00285-01*} {*AI05-0262-1*} {*AI05-0264-1*} The function returns an image of the value of *Arg* as a *Wide\_String*. The lower bound of the result is one. The image has the same sequence of graphic characters as defined for *S**Wide\_Wide\_Image* if all the graphic characters are defined in *Wide\_Character*; otherwise, the sequence of characters is implementation defined (but no shorter than that of *S**Wide\_Wide\_Image* for the same value of *Arg*).
- 30.a/2 **Implementation defined:** The sequence of characters of the value returned by *S**Wide\_Image* when some of the graphic characters of *S**Wide\_Wide\_Image* are not defined in *Wide\_Character*.  
*Paragraphs 31 through 34 were moved to Wide\_Wide\_Image.*
- 35 *S**Image* *S**Image* denotes a function with the following specification:
- 36       **function** *S**Image* (*Arg* : *S**Base*)  
          **return** *String*
- 37/3       {*AI95-00285-01*} {*AI05-0264-1*} The function returns an image of the value of *Arg* as a *String*. The lower bound of the result is one. The image has the same sequence of graphic characters as that defined for *S**Wide\_Wide\_Image* if all the graphic characters are defined in *Character*; otherwise, the sequence of characters is implementation defined (but no shorter than that of *S**Wide\_Wide\_Image* for the same value of *Arg*).

It denotes zero for a subtype that has a null range. Its type is <i>universal_integer</i> .                                                                                                                                                                                                                                                                                                                                                           | 38       |
| S'Width                        | S'Width denotes the maximum length of a String returned by S'Image over all values of the subtype S. It denotes zero for a subtype that has a null range. Its type is <i>universal_integer</i> .                                                                                                                                                                                                                                                                                                                                                                          | 39       |
| S'Wide_Wide_Value              | <i>{AI95-00285-01}</i> S'Wide_Wide_Value denotes a function with the following specification:                                                                                                                                                                                                                                                                                                                                                                                                                                                                             | 39.1/2   |
|                                | <pre>function S'Wide_Wide_Value (Arg : Wide_Wide_String) return S'Base</pre>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              | 39.2/2   |
|                                | This function returns a value given an image of the value as a Wide_Wide_String, ignoring any leading or trailing spaces.                                                                                                                                                                                                                                                                                                                                                                                                                                                 | 39.3/2   |
|                                | <i>{AI05-0264-1}</i> For the evaluation of a call on S'Wide_Wide_Value for an enumeration subtype S, if the sequence of characters of the parameter (ignoring leading and trailing spaces) has the syntax of an enumeration literal and if it corresponds to a literal of the type of S (or corresponds to the result of S'Wide_Wide_Image for a nongraphic character of the type), the result is the corresponding enumeration value; otherwise, Constraint_Error is raised.                                                                                             | 39.4/3   |
| <b>Discussion:</b>             | It's not crystal clear that Range_Check is appropriate here, but it doesn't seem worthwhile to invent a whole new check name just for this weird case, so we decided to lump it in with Range_Check.                                                                                                                                                                                                                                                                                                                                                                      | 39.a.1/2 |
| <b>To be honest:</b>           | <i>{8652/0096}</i> <i>{AI95-00053-01}</i> A sequence of characters corresponds to the result of S'Wide_Wide_Image if it is the same ignoring case. Thus, the case of an image of a nongraphic character does not matter. For example, Character'Wide_Wide_Value("nul") does not raise Constraint_Error, even though Character'Wide_Wide_Image returns "NUL" for the nul character.                                                                                                                                                                                        | 39.a.2/2 |
|                                | <i>{AI05-0264-1}</i> For the evaluation of a call on S'Wide_Wide_Value for an integer subtype S, if the sequence of characters of the parameter (ignoring leading and trailing spaces) has the syntax of an integer literal, with an optional leading sign character (plus or minus for a signed type; only plus for a modular type), and the corresponding numeric value belongs to the base range of the type of S, then that value is the result; otherwise, Constraint_Error is raised.                                                                               | 39.5/3   |
| <b>Discussion:</b>             | We considered allowing 'Value to return a representable but out-of-range value without a Constraint_Error. However, we currently require (see 4.9) in an assignment_statement like "X := <numeric_literal>," that the value of the numeric-literal be in X's base range (at compile time), so it seems unfriendly and confusing to have a different range allowed for 'Value. Furthermore, for modular types, without the requirement for being in the base range, 'Value would have to handle arbitrarily long literals (since overflow never occurs for modular types). | 39.a.3/2 |
|                                | For the evaluation of a call on S'Wide_Wide_Value for a real subtype S, if the sequence of characters of the parameter (ignoring leading and trailing spaces) has the syntax of one of the following:                                                                                                                                                                                                                                                                                                                                                                     | 39.6/2   |

39.12/3 *{AI05-0264-1}* with an optional leading sign character (plus or minus), and if the corresponding numeric value belongs to the base range of the type of S, then that value is the result; otherwise, `Constraint_Error` is raised. The sign of a zero value is preserved (positive if none has been specified) if `S'Signed_Zeros` is `True`.

40 `S'Wide_Value`

`S'Wide_Value` denotes a function with the following specification:

```
41 function S'Wide_Value(Arg : Wide_String)
 return S'Base
```

42 This function returns a value given an image of the value as a `Wide_String`, ignoring any leading or trailing spaces.

43/3 *{AI95-00285-01}* *{AI05-0264-1}* For the evaluation of a call on `S'Wide_Value` for an enumeration subtype S, if the sequence of characters of the parameter (ignoring leading and trailing spaces) has the syntax of an enumeration literal and if it corresponds to a literal of the type of S (or corresponds to the result of `S'Wide_Image` for a value of the type), the result is the corresponding enumeration value; otherwise, `Constraint_Error` is raised. For a numeric subtype S, the evaluation of a call on `S'Wide_Value` with *Arg* of type `Wide_String` is equivalent to a call on `S'Wide_Wide_Value` for a corresponding *Arg* of type `Wide_Wide_String`.

43.a/2 *This paragraph was deleted.*

43.a.1/2 *This paragraph was deleted. {8652/0096} {AI95-00053-01}*

43.b/2 **Reason:** `S'Wide_Value` is subtly different from `S'Wide_Wide_Value` for enumeration subtypes since `S'Wide_Image` might produce a different sequence of characters than `S'Wide_Wide_Image` if the enumeration literal uses characters outside of the predefined type `Wide_Character`. That is why we don't just define `S'Wide_Value` in terms of `S'Wide_Wide_Value` for enumeration subtypes. `S'Wide_Value` and `S'Wide_Wide_Value` for numeric subtypes yield the same result given the same sequence of characters.

*Paragraphs 44 through 51 were moved to `Wide_Wide_Value`.*

52 `S'Value` `S'Value` denotes a function with the following specification:

```
53 function S'Value(Arg : String)
 return S'Base
```

54 This function returns a value given an image of the value as a `String`, ignoring any leading or trailing spaces.

55/3 *{AI95-00285-01}* *{AI05-0264-1}* For the evaluation of a call on `S'Value` for an enumeration subtype S, if the sequence of characters of the parameter (ignoring leading and trailing spaces) has the syntax of an enumeration literal and if it corresponds to a literal of the type of S (or corresponds to the result of `S'Image` for a value of the type), the result is the corresponding enumeration value; otherwise, `Constraint_Error` is raised. For a numeric subtype S, the evaluation of a call on `S'Value` with *Arg* of type `String` is equivalent to a call on `S'Wide_Wide_Value` for a corresponding *Arg* of type `Wide_Wide_String`.

55.a/2 **Reason:** *{AI95-00285-01}* `S'Value` is subtly different from `S'Wide_Wide_Value` for enumeration subtypes; see the discussion under `S'Wide_Value`.

#### *Implementation Permissions*

56/2 *{AI95-00285-01}* An implementation may extend the `Wide_Wide_Value`, [`Wide_Value`, `Value`, `Wide_Wide_Image`, `Wide_Image`, and `Image`] attributes of a floating point type to support special values such as infinities and NaNs.

56.a/2 **Proof:** *{AI95-00285-01}* The permission is really only necessary for `Wide_Wide_Value`, because `Value` and `Wide_Value` are defined in terms of `Wide_Wide_Value`, and because the behavior of `Wide_Wide_Image`, `Wide_Image`, and `Image` is already unspecified for things like infinities and NaNs.

56.b **Reason:** This is to allow implementations to define full support for IEEE arithmetic. See also the similar permission for `Get` in A.10.9.

{AI05-0182-1} {AI05-0262-1} {AI05-0269-1} An implementation may extend the `Wide_Wide_Value`, `Wide_Value`, and `Value` attributes of a character type to accept strings of the form “Hex\_ *hhhhhhh*” (ignoring case) for any character (not just the ones for which `Wide_Wide_Image` would produce that form — see 3.5.2), as well as three-character strings of the form “*X*”, where *X* is any character, including nongraphic characters. 56.1/3

#### Static Semantics

{AI05-0228-1} For a scalar type, the following language-defined representation aspect may be specified with an `aspect_specification` (see 13.1.1): 56.2/3

`Default_Value` 56.3/3

This aspect shall be specified by a static expression, and that expression shall be explicit, even if the aspect has a boolean type. `Default_Value` shall be specified only on a `full_type_declaration`.

**Reason:** The part about requiring an explicit expression is to disallow omitting the value for this aspect, which would otherwise be allowed by the rules of 13.1.1. 56.c/3

This is a representation aspect in order to disallow specifying it on a derived type that has inherited primitive subprograms; that is necessary as the sizes of `out` parameters could be different whether or not a `Default_Value` is specified (see 6.4.1). 56.d/3

**Aspect Description for `Default_Value`:** Default value for a scalar subtype. 56.e/3

{AI05-0228-1} If a derived type with no primitive subprograms inherits a boolean `Default_Value` aspect, the aspect may be specified to have any value for the derived type. 56.4/3

**Reason:** This overrides the 13.1.1 rule that says that a boolean aspect with a value `True` cannot be changed. 56.f/3

#### Name Resolution Rules

{AI05-0228-1} The expected type for the `expression` specified for the `Default_Value` aspect is the type defined by the `full_type_declaration` on which it appears. 56.5/3

#### NOTES

24 The evaluation of `S'First` or `S'Last` never raises an exception. If a scalar subtype `S` has a nonnull range, `S'First` and `S'Last` belong to this range. These values can, for example, always be assigned to a variable of subtype `S`. 57

**Discussion:** This paragraph addresses an issue that came up with Ada 83, where for fixed point types, the end points of the range specified in the type definition were not necessarily within the base range of the type. However, it was later clarified (and we reconfirm it in 3.5.9, “Fixed Point Types”) that the `First` and `Last` attributes reflect the true bounds chosen for the type, not the bounds specified in the type definition (which might be outside the ultimately chosen base range). 57.a

25 For a subtype of a scalar type, the result delivered by the attributes `Succ`, `Pred`, and `Value` might not belong to the subtype; similarly, the actual parameters of the attributes `Succ`, `Pred`, and `Image` need not belong to the subtype. 58

26 For any value `V` (including any nongraphic character) of an enumeration subtype `S`, `S'Value(S'Image(V))` equals `V`, as do `S'Wide_Value(S'Wide_Image(V))` and `S'Wide_Wide_Value(S'Wide_Wide_Image(V))`. None of these expressions ever raise `Constraint_Error`. 59

#### Examples

*Examples of ranges:* 60

```
-10 .. 10 61
X .. X + 1
0.0 .. 2.0*Pi
Red .. Green -- see 3.5.1
1 .. 0 -- a null range
Table'Range -- a range attribute reference (see 3.6)
```

*Examples of range constraints:* 62

```
range -999.0 .. +999.0 63
range S'First+1 .. S'Last-1
```

*Incompatibilities With Ada 83*

- 63.a/1 S'Base is no longer defined for nonscalar types. One conceivable existing use of S'Base for nonscalar types is S'Base'Size where S is a generic formal private type. However, that is not generally useful because the actual subtype corresponding to S might be a constrained array or discriminated type, which would mean that S'Base'Size might very well overflow (for example, S'Base'Size where S is a constrained subtype of String will generally be 8 \* (Integer'Last + 1)). For derived discriminated types that are packed, S'Base'Size might not even be well defined if the first subtype is constrained, thereby allowing some amount of normally required “dope” to have been squeezed out in the packing. Hence our conclusion is that S'Base'Size is not generally useful in a generic, and does not justify keeping the attribute Base for nonscalar types just so it can be used as a prefix.

*Extensions to Ada 83*

- 63.b The attribute S'Base for a scalar subtype is now permitted anywhere a subtype\_mark is permitted. S'Base'First .. S'Base'Last is the base range of the type. Using an attribute\_definition\_clause, one cannot specify any subtype-specific attributes for the subtype denoted by S'Base (the base subtype).
- 63.c The attribute S'Range is now allowed for scalar subtypes.
- 63.d The attributes S'Min and S'Max are now defined, and made available for all scalar types.
- 63.e The attributes S'Succ, S'Pred, S'Image, S'Value, and S'Width are now defined for real types as well as discrete types.
- 63.f Wide\_String versions of S'Image and S'Value are defined. These are called S'Wide\_Image and S'Wide\_Value to avoid introducing ambiguities involving uses of these attributes with string literals.

*Wording Changes from Ada 83*

- 63.g We now use the syntactic category range\_attribute\_reference since it is now syntactically distinguished from other attribute references.
- 63.h The definition of S'Base has been moved here from 3.3.3 since it now applies only to scalar types.
- 63.i More explicit rules are provided for nongraphic characters.

*Extensions to Ada 95*

- 63.j/2 {AI95-00285-01} The attributes Wide\_Wide\_Image, Wide\_Wide\_Value, and Wide\_Wide\_Width are new. Note that Wide\_Image and Wide\_Value are now defined in terms of Wide\_Wide\_Image and Wide\_Wide\_Value, but the image of types other than characters have not changed.

*Wording Changes from Ada 95*

- 63.k/2 {AI95-00285-01} The Wide\_Image and Wide\_Value attributes are now defined in terms of Wide\_Wide\_Image and Wide\_Wide\_Value, but the images of numeric types have not changed.

*Inconsistencies With Ada 2005*

- 63.l/3 {AI05-0181-1} **Correction:** Soft hyphen (code point 173) is nongraphic in ISO/IEC 10646:2011 (and also in the 2003 version of that standard). Thus, we have given it the language-defined name *soft\_hyphen*. This changes the result of Character'Image (and all of the related types and Image attributes) for this character, and changes the behavior of Character'Value (and all of the related types and Value attributes) for this character, and (in unusual circumstances), changes the result for Character'Width (and all of the related types and Width attributes). The vast majority of programs won't see any difference, as they are already prepared to handle nongraphic characters.
- 63.m/3 {AI05-0182-1} **Correction:** Added an Implementation Permissions to let Wide\_Wide\_Value, Wide\_Value, and Value accept strings in the form of literals containing nongraphic characters and "Hex\_hhhhhhhh" for Latin-1 and graphic characters. These were required to raise Constraint\_Error in Ada 2005. Since these attributes aren't very useful, implementations were inconsistent as to whether these were accepted, and since code that would care why the attribute failed seems unlikely, this should not be a problem in practice.

*Extensions to Ada 2005*

- 63.n/3 {AI05-0228-1} The new aspect Default\_Value allows defining implicit initial values (see 3.3.1) for scalar types.

### 3.5.1 Enumeration Types

- 1 [ An enumeration\_type\_definition defines an enumeration type.]

*Syntax*

enumeration\_type\_definition ::= 2  
 (enumeration\_literal\_specification {, enumeration\_literal\_specification})  
 enumeration\_literal\_specification ::= defining\_identifier | defining\_character\_literal 3  
 defining\_character\_literal ::= character\_literal 4

*Legality Rules*

{AI05-0227-1} {AI05-0299-1} The defining\_identifiers in upper case [and the 5/3  
 defining\_character\_literals] listed in an enumeration\_type\_definition shall be distinct.

**Proof:** {AI05-0227-1} For character literals, this is a ramification of the normal disallowance of homographs explicitly 5.a/3  
 declared immediately in the same declarative region.

**Reason:** {AI05-0227-1} To ease implementation of the attribute Wide\_Wide\_Value, we require that all enumeration 5.b/3  
 literals have distinct images.

*Static Semantics*

{AI05-0006-1} Each enumeration\_literal\_specification is the explicit declaration of the corresponding 6/3  
*enumeration literal*: it declares a parameterless function, whose defining name is the defining\_identifier  
 or defining\_character\_literal, and whose result subtype is the base subtype of the enumeration type.

**Reason:** This rule defines the profile of the enumeration literal, which is used in the various types of conformance. 6.a

**Ramification:** The parameterless function associated with an enumeration literal is fully defined by the 6.b  
 enumeration\_type\_definition; a body is not permitted for it, and it never fails the Elaboration\_Check when called.

**Discussion:** {AI05-0006-1} The result subtype is primarily a concern when an enumeration literal is used as the 6.c/3  
 expression of a case statement, due to the full coverage requirement based on the nominal subtype.

Each enumeration literal corresponds to a distinct value of the enumeration type, and to a distinct position 7  
 number. The position number of the value of the first listed enumeration literal is zero; the position  
 number of the value of each subsequent enumeration literal is one more than that of its predecessor in the  
 list.

[The predefined order relations between values of the enumeration type follow the order of corresponding 8  
 position numbers.]

[ If the same defining\_identifier or defining\_character\_literal is specified in more than one 9  
 enumeration\_type\_definition, the corresponding enumeration literals are said to be *overloaded*. At any  
 place where an overloaded enumeration literal occurs in the text of a program, the type of the enumeration  
 literal has to be determinable from the context (see 8.6).]

*Dynamic Semantics*

The elaboration of an enumeration\_type\_definition creates the enumeration type and its first subtype, 10  
 which is constrained to the base range of the type.

**Ramification:** The first subtype of a discrete type is always constrained, except in the case of a derived type whose 10.a  
 parent subtype is Whatever'Base.

When called, the parameterless function associated with an enumeration literal returns the corresponding 11  
 value of the enumeration type.

## NOTES

27 If an enumeration literal occurs in a context that does not otherwise suffice to determine the type of the literal, then 12  
 qualification by the name of the enumeration type is one way to resolve the ambiguity (see 4.7).

## Examples

13 *Examples of enumeration types and subtypes:*

```

14 type Day is (Mon, Tue, Wed, Thu, Fri, Sat, Sun);
14 type Suit is (Clubs, Diamonds, Hearts, Spades);
14 type Gender is (M, F);
14 type Level is (Low, Medium, Urgent);
14 type Color is (White, Red, Yellow, Green, Blue, Brown, Black);
14 type Light is (Red, Amber, Green); -- Red and Green are overloaded
15 type Hexa is ('A', 'B', 'C', 'D', 'E', 'F');
15 type Mixed is ('A', 'B', '*', B, None, '?', '%');
16 subtype Weekday is Day range Mon .. Fri;
16 subtype Major is Suit range Hearts .. Spades;
16 subtype Rainbow is Color range Red .. Blue; -- the Color Red, not the Light

```

## Wording Changes from Ada 83

16.a The syntax rule for defining `character_literal` is new. It is used for the defining occurrence of a `character_literal`, analogously to `defining_identifier`. Usage occurrences use the name or `selector_name` syntactic categories.

16.b We emphasize the fact that an enumeration literal denotes a function, which is called to produce a value.

## Incompatibilities With Ada 2005

16.c/3 {AI05-0227-1} **Correction:** Required that all enumeration literals in a type have distinct images; this might not be the case since upper case conversion can map distinct characters to the same upper case character. This can only happen for identifiers using Unicode characters first allowed by Ada 2005; moreover, the original definition of Ada 2005 was confused and appeared to require inconsistent results from the `Image` attribute, so implementations that allowed problematic cases are rare; the problematic cases are very rare; so it is expected that this change would only affect test programs.

## Wording Changes from Ada 2005

16.d/3 {AI05-0006-1} **Correction:** Defined the result subtype of an enumeration literal to close a minor language hole.

## 3.5.2 Character Types

## Static Semantics

1 An enumeration type is said to be a *character type* if at least one of its enumeration literals is a `character_literal`.

2/3 {AI95-00285-01} {AI05-0181-1} {AI05-0262-1} {AI05-0266-1} The predefined type `Character` is a character type whose values correspond to the 256 code points of Row 00 (also known as Latin-1) of the ISO/IEC 10646:2011 Basic Multilingual Plane (BMP). Each of the graphic characters of Row 00 of the BMP has a corresponding `character_literal` in `Character`. Each of the nongraphic characters of Row 00 has a corresponding language-defined name, which is not usable as an enumeration literal, but which is usable with the attributes `Image`, `Wide_Image`, `Wide_Wide_Image`, `Value`, `Wide_Value`, and `Wide_Wide_Value`; these names are given in the definition of type `Character` in A.1, “The Package Standard”, but are set in *italics*.

2.a/3 **Discussion:** {AI05-0262-1} `Code_point` is defined in ISO/IEC 10646:2011.

3/3 {AI95-00285-01} {AI05-0262-1} The predefined type `Wide_Character` is a character type whose values correspond to the 65536 code points of the ISO/IEC 10646:2011 Basic Multilingual Plane (BMP). Each of the graphic characters of the BMP has a corresponding `character_literal` in `Wide_Character`. The first 256 values of `Wide_Character` have the same `character_literal` or language-defined name as defined for `Character`. Each of the `graphic_characters` has a corresponding `character_literal`.

4/3 {AI95-00285-01} {AI05-0262-1} The predefined type `Wide_Wide_Character` is a character type whose values correspond to the 2147483648 code points of the ISO/IEC 10646:2011 character set. Each of the

`graphic_characters` has a corresponding `character_literal` in `Wide_Wide_Character`. The first 65536 values of `Wide_Wide_Character` have the same `character_literal` or language-defined name as defined for `Wide_Character`.

{AI95-00285-01} {AI05-0262-1} The characters whose code point is larger than 16#FF# and which are not `graphic_characters` have language-defined names which are formed by appending to the string "Hex\_" the representation of their code point in hexadecimal as eight extended digits. As with other language-defined names, these names are usable only with the attributes `(Wide_)Wide_Image` and `(Wide_)Wide_Value`; they are not usable as enumeration literals. 5/3

**Reason:** {AI95-00285-01} The language-defined names are not usable as enumeration literals to avoid "polluting" the name space. Since `Wide_Character` and `Wide_Wide_Character` are defined in Standard, if the language-defined names were usable as enumeration literals, they would hide other nonoverloadable declarations with the same names in `use-d` packages.}] 5.a/2

*Paragraphs 6 and 7 were deleted.*

#### NOTES

28 The language-defined library package `Characters.Latin_1` (see A.3.3) includes the declaration of constants denoting control characters, lower case characters, and special characters of the predefined type `Character`. 8

**To be honest:** The package `ASCII` does the same, but only for the first 128 characters of `Character`. Hence, it is an obsolescent package, and we no longer mention it here. 8.a

29 {AI05-0299-1} A conventional character set such as `EBCDIC` can be declared as a character type; the internal codes of the characters can be specified by an `enumeration_representation_clause` as explained in subclause 13.4. 9/3

#### Examples

*Example of a character type:*

```
type Roman_Digit is ('I', 'V', 'X', 'L', 'C', 'D', 'M');
```

10  
11

#### *Inconsistencies With Ada 83*

The declaration of `Wide_Character` in package `Standard` hides use-visible declarations with the same defining identifier. In the unlikely event that an Ada 83 program had depended on such a use-visible declaration, and the program remains legal after the substitution of `Standard.Wide_Character`, the meaning of the program will be different. 11.a

#### *Incompatibilities With Ada 83*

The presence of `Wide_Character` in package `Standard` means that an expression such as 11.b

```
'a' = 'b'
```

11.c

is ambiguous in Ada 95, whereas in Ada 83 both literals could be resolved to be of type `Character`. 11.d

The change in visibility rules (see 4.2) for character literals means that additional qualification might be necessary to resolve expressions involving overloaded subprograms and character literals. 11.e

#### *Extensions to Ada 83*

The type `Character` has been extended to have 256 positions, and the type `Wide_Character` has been added. Note that this change was already approved by the ARG for Ada 83 conforming compilers. 11.f

The rules for referencing character literals are changed (see 4.2), so that the declaration of the character type need not be directly visible to use its literals, similar to `null` and string literals. Context is used to resolve their type. 11.g

#### *Inconsistencies With Ada 95*

{AI95-00285-01} Ada 95 defined most characters in `Wide_Character` to be graphic characters, while Ada 2005 uses the categorizations from ISO-10646:2003. It also provides language-defined names for all nongraphic characters. That means that in Ada 2005, `Wide_Character'Wide_Value` will raise `Constraint_Error` for a string representing a `character_literal` of a nongraphic character, while Ada 95 would have accepted it. Similarly, the result of `Wide_Character'Wide_Image` will change for such nongraphic characters. 11.h/2

{AI95-00395-01} {AI05-0005-1} {AI05-0262-1} The language-defined names `FFFE` and `FFFF` were replaced by a consistent set of language-defined names for all nongraphic characters with code points greater than 16#FF#. That means that in Ada 2005, `Wide_Character'Wide_Value("FFFF")` will raise `Constraint_Error` while Ada 95 would have 11.i/3

accepted it. Similarly, the result of `Wide_Character'Wide_Image` will change for the position numbers `16#FFFE#` and `16#FFFF#`. It is very unlikely that this will matter in practice, as these names do not represent usable characters.

11.j/2 {AI95-00285-01} {AI95-00395-01} Because of the previously mentioned changes to the `Wide_Character'Wide_Image` of various character values, the value of attribute `Wide_Width` will change for some subtypes of `Wide_Character`. However, the new language-defined names were chosen so that the value of `Wide_Character'Wide_Width` itself does not change.

11.k/2 {AI95-00285-01} The declaration of `Wide_Wide_Character` in package `Standard` hides use-visible declarations with the same defining identifier. In the (very) unlikely event that an Ada 95 program had depended on such a use-visible declaration, and the program remains legal after the substitution of `Standard.Wide_Wide_Character`, the meaning of the program will be different.

#### *Extensions to Ada 95*

11.l/2 {AI95-00285-01} The type `Wide_Wide_Character` is new.

#### *Wording Changes from Ada 95*

11.m/2 {AI95-00285-01} Characters are now defined in terms of the entire ISO/IEC 10646:2003 character set.

11.n/3 {AI95-00285-01} {AI05-0248-1} We dropped the Implementation Advice for nonstandard interpretation of character sets; an implementation can do what it wants in a nonstandard mode, so there isn't much point to any advice.

#### *Wording Changes from Ada 2005*

11.o/3 {AI05-0181-1} **Correction:** Removed the position numbers of nongraphic characters from the text, as it is wrong and thus misleading.

11.p/3 {AI05-0262-1} Changed "code position" to "code point" consistently throughout the standard, as ISO/IEC 10646:2011 prefers "code point" and we are referring to the definition in that Standard. This change also reduces confusion between "code point" and "position number"; while these have the same values for the predefined character types, there is no required relationship for other character types.

## 3.5.3 Boolean Types

### *Static Semantics*

1 There is a predefined enumeration type named `Boolean`, [declared in the visible part of package `Standard`]. It has the two enumeration literals `False` and `True` ordered with the relation `False < True`. Any descendant of the predefined type `Boolean` is called a *boolean* type.

1.a **Implementation Note:** An implementation is not required to support enumeration representation clauses on boolean types that impose an unacceptable implementation burden. See 13.4, "Enumeration Representation Clauses". However, it is generally straightforward to support representations where `False` is zero and `True` is  $2^{**n} - 1$  for some  $n$ .

## 3.5.4 Integer Types

1 An `integer_type_definition` defines an integer type; it defines either a *signed* integer type, or a *modular* integer type. The base range of a signed integer type includes at least the values of the specified range. A modular type is an integer type with all arithmetic modulo a specified positive *modulus*; such a type corresponds to an unsigned type with wrap-around semantics.

### *Syntax*

2 `integer_type_definition ::= signed_integer_type_definition | modular_type_definition`

3 `signed_integer_type_definition ::= range static_simple_expression .. static_simple_expression`

3.a **Discussion:** We don't call this a `range_constraint`, because it is rather different — not only is it required to be static, but the associated overload resolution rules are different than for normal range constraints. A similar comment applies to `real_range_specification`. This used to be `integer_range_specification` but when we added support for modular types, it seemed overkill to have three levels of syntax rules, and just calling these `signed_integer_range_specification` and `modular_range_specification` loses the fact that they are defining different classes of types, which is important for the generic type matching rules.

modular\_type\_definition ::= **mod** *static\_expression* 4

*Name Resolution Rules*

Each *simple\_expression* in a *signed\_integer\_type\_definition* is expected to be of any integer type; they need not be of the same type. The *expression* in a *modular\_type\_definition* is likewise expected to be of any integer type. 5

*Legality Rules*

The *simple\_expressions* of a *signed\_integer\_type\_definition* shall be static, and their values shall be in the range `System.Min_Int .. System.Max_Int`. 6

The *expression* of a *modular\_type\_definition* shall be static, and its value (the *modulus*) shall be positive, and shall be no greater than `System.Max_Binary_Modulus` if a power of 2, or no greater than `System.Max_Nonbinary_Modulus` if not. 7

**Reason:** For a 2's-complement machine, supporting nonbinary moduli greater than `System.Max_Int` can be quite difficult, whereas essentially any binary moduli are straightforward to support, up to  $2 * \text{System.Max\_Int} + 2$ , so this justifies having two separate limits. 7.a

*Static Semantics*

The set of values for a signed integer type is the (infinite) set of mathematical integers[, though only values of the base range of the type are fully supported for run-time operations]. The set of values for a modular integer type are the values from 0 to one less than the modulus, inclusive. 8

A *signed\_integer\_type\_definition* defines an integer type whose base range includes at least the values of the *simple\_expressions* and is symmetric about zero, excepting possibly an extra negative value. A *signed\_integer\_type\_definition* also defines a constrained first subtype of the type, with a range whose bounds are given by the values of the *simple\_expressions*, converted to the type being defined. 9

**Implementation Note:** {A195-00114-01} The base range of a signed integer type might be much larger than is necessary to satisfy the above requirements. 9.a/2

**To be honest:** The conversion mentioned above is not an *implicit subtype conversion* (which is something that happens at overload resolution, see 4.6), although it happens implicitly. Therefore, the freezing rules are not invoked on the type (which is important so that representation items can be given for the type). 9.a.1/1

A *modular\_type\_definition* defines a modular type whose base range is from zero to one less than the given modulus. A *modular\_type\_definition* also defines a constrained first subtype of the type with a range that is the same as the base range of the type. 10

There is a predefined signed integer subtype named `Integer`[, declared in the visible part of package `Standard`]. It is constrained to the base range of its type. 11

**Reason:** `Integer` is a constrained subtype, rather than an unconstrained subtype. This means that on assignment to an object of subtype `Integer`, a range check is required. On the other hand, an object of subtype `Integer'Base` is unconstrained, and no range check (only overflow check) is required on assignment. For example, if the object is held in an extended-length register, its value might be outside of `Integer'First .. Integer'Last`. All parameter and result subtypes of the predefined integer operators are of such unconstrained subtypes, allowing extended-length registers to be used as operands or for the result. In an earlier version of Ada 95, `Integer` was unconstrained. However, the fact that certain `Constraint_Errors` might be omitted or appear elsewhere was felt to be an undesirable upward inconsistency in this case. Note that for `Float`, the opposite conclusion was reached, partly because of the high cost of performing range checks when not actually necessary. Objects of subtype `Float` are unconstrained, and no range checks, only overflow checks, are performed for them. 11.a

`Integer` has two predefined subtypes, [declared in the visible part of package `Standard`:] 12

```
subtype Natural is Integer range 0 .. Integer'Last;
subtype Positive is Integer range 1 .. Integer'Last;
```

13

14 A type defined by an `integer_type_definition` is implicitly derived from `root_integer`, an anonymous predefined (specific) integer type, whose base range is `System.Min_Int .. System.Max_Int`. However, the base range of the new type is not inherited from `root_integer`, but is instead determined by the range or modulus specified by the `integer_type_definition`. [Integer literals are all of the type `universal_integer`, the universal type (see 3.4.1) for the class rooted at `root_integer`, allowing their use with the operations of any integer type.]

14.a **Discussion:** This implicit derivation is not considered exactly equivalent to explicit derivation via a `derived_type_definition`. In particular, integer types defined via a `derived_type_definition` inherit their base range from their parent type. A type defined by an `integer_type_definition` does not necessarily inherit its base range from `root_integer`. It is not specified whether the implicit derivation from `root_integer` is direct or indirect, not that it really matters. All we want is for all integer types to be descendants of `root_integer`.

14.a.1/1 {8652/0099} {AI95-00152-01} Note that this derivation does not imply any inheritance of subprograms. Subprograms are inherited only for types derived by a `derived_type_definition` (see 3.4), or a `private_extension_declaration` (see 7.3, 7.3.1, and 12.5.1).

14.b **Implementation Note:** It is the intent that even nonstandard integer types (see below) will be descendants of `root_integer`, even though they might have a base range that exceeds that of `root_integer`. This causes no problem for static calculations, which are performed without range restrictions (see 4.9). However for run-time calculations, it is possible that `Constraint_Error` might be raised when using an operator of `root_integer` on the result of `'Val` applied to a value of a nonstandard integer type.

15 The *position number* of an integer value is equal to the value.

16/2 {AI95-00340-01} For every modular subtype S, the following attributes are defined:

16.1/2 S'Mod {AI95-00340-01} S'Mod denotes a function with the following specification:

```
16.2/2 function S'Mod (Arg : universal_integer)
 return S'Base
```

16.3/2 This function returns *Arg mod S'Modulus*, as a value of the type of S.

17 S'Modulus S'Modulus yields the modulus of the type of S, as a value of the type `universal_integer`.

#### Dynamic Semantics

18 The elaboration of an `integer_type_definition` creates the integer type and its first subtype.

19 For a modular type, if the result of the execution of a predefined operator (see 4.5) is outside the base range of the type, the result is reduced modulo the modulus of the type to a value that is within the base range of the type.

20 For a signed integer type, the exception `Constraint_Error` is raised by the execution of an operation that cannot deliver the correct result because it is outside the base range of the type. [ For any integer type, `Constraint_Error` is raised by the operators `"/`, `"rem`", and `"mod`" if the right operand is zero.]

#### Implementation Requirements

21 In an implementation, the range of Integer shall include the range  $-2^{15}+1 .. +2^{15}-1$ .

22 If `Long_Integer` is predefined for an implementation, then its range shall include the range  $-2^{31}+1 .. +2^{31}-1$ .

23 `System.Max_Binary_Modulus` shall be at least  $2^{16}$ .

#### Implementation Permissions

24 For the execution of a predefined operation of a signed integer type, the implementation need not raise `Constraint_Error` if the result is outside the base range of the type, so long as the correct result is produced.

- Discussion:** Constraint\_Error is never raised for operations on modular types, except for divide-by-zero (and rem/mod-by-zero). 24.a
- An implementation may provide additional predefined signed integer types[, declared in the visible part of Standard], whose first subtypes have names of the form Short\_Integer, Long\_Integer, Short\_Short\_Integer, Long\_Long\_Integer, etc. Different predefined integer types are allowed to have the same base range. However, the range of Integer should be no wider than that of Long\_Integer. Similarly, the range of Short\_Integer (if provided) should be no wider than Integer. Corresponding recommendations apply to any other predefined integer types. There need not be a named integer type corresponding to each distinct base range supported by an implementation. The range of each first subtype should be the base range of its type. 25
- Implementation defined:** The predefined integer types declared in Standard. 25.a
- An implementation may provide *nonstandard integer types*, descendants of *root\_integer* that are declared outside of the specification of package Standard, which need not have all the standard characteristics of a type defined by an integer\_type\_definition. For example, a nonstandard integer type might have an asymmetric base range or it might not be allowed as an array or loop index (a very long integer). Any type descended from a nonstandard integer type is also nonstandard. An implementation may place arbitrary restrictions on the use of such types; it is implementation defined whether operators that are predefined for “any integer type” are defined for a particular nonstandard integer type. [In any case, such types are not permitted as explicit\_generic\_actual\_parameters for formal scalar types — see 12.5.2.] 26
- Implementation defined:** Any nonstandard integer types and the operators defined for them. 26.a
- For a one's complement machine, the high bound of the base range of a modular type whose modulus is one less than a power of 2 may be equal to the modulus, rather than one less than the modulus. It is implementation defined for which powers of 2, if any, this permission is exercised. 27
- {8652/0003} {AI95-00095-01} For a one's complement machine, implementations may support nonbinary modulus values greater than System.Max\_Nonbinary\_Modulus. It is implementation defined which specific values greater than System.Max\_Nonbinary\_Modulus, if any, are supported. 27.1/1
- Reason:** On a one's complement machine, the natural full word type would have a modulus of 2\*\*Word\_Size-1. However, we would want to allow the all-ones bit pattern (which represents negative zero as a number) in logical operations. These permissions are intended to allow that and the natural modulus value without burdening implementations with supporting expensive modulus values. 27.a.1/2
- Implementation Advice*
- An implementation should support Long\_Integer in addition to Integer if the target machine supports 32-bit (or longer) arithmetic. No other named integer subtypes are recommended for package Standard. Instead, appropriate named integer subtypes should be provided in the library package Interfaces (see B.2). 28
- Implementation Advice:** Long\_Integer should be declared in Standard if the target supports 32-bit arithmetic. No other named integer subtypes should be declared in Standard. 28.a.1/2
- Implementation Note:** To promote portability, implementations should explicitly declare the integer (sub)types Integer and Long\_Integer in Standard, and leave other predefined integer types anonymous. For implementations that already support Byte\_Integer, etc., upward compatibility argues for keeping such declarations in Standard during the transition period, but perhaps generating a warning on use. A separate package Interfaces in the predefined environment is available for pre-declaring types such as Integer\_8, Integer\_16, etc. See B.2. In any case, if the user declares a subtype (first or not) whose range fits in, for example, a byte, the implementation can store variables of the subtype in a single byte, even if the base range of the type is wider. 28.a
- An implementation for a two's complement machine should support modular types with a binary modulus up to System.Max\_Int\*2+2. An implementation should support a nonbinary modulus up to Integer'Last. 29
- Implementation Advice:** For a two's complement target, modular types with a binary modulus up to System.Max\_Int\*2+2 should be supported. A nonbinary modulus up to Integer'Last should be supported. 29.a.1/2

- 29.a **Reason:** Modular types provide bit-wise "and", "or", "xor", and "not" operations. It is important for systems programming that these be available for all integer types of the target hardware.
- 29.b **Ramification:** Note that on a one's complement machine, the largest supported modular type would normally have a nonbinary modulus. On a two's complement machine, the largest supported modular type would normally have a binary modulus.
- 29.c **Implementation Note:** Supporting a nonbinary modulus greater than Integer'Last can impose an undesirable implementation burden on some machines.

## NOTES

- 30 Integer literals are of the anonymous predefined integer type *universal\_integer*. Other integer types have no literals. However, the overload resolution rules (see 8.6, "The Context of Overload Resolution") allow expressions of the type *universal\_integer* whenever an integer type is expected.
- 31 The same arithmetic operators are predefined for all signed integer types defined by a *signed\_integer\_type\_definition* (see 4.5, "Operators and Expression Evaluation"). For modular types, these same operators are predefined, plus bit-wise logical operators (**and**, **or**, **xor**, and **not**). In addition, for the unsigned types declared in the language-defined package Interfaces (see B.2), functions are defined that provide bit-wise shifting and rotating.
- 32 Modular types match a *generic\_formal\_parameter\_declaration* of the form "type T is mod <>"; signed integer types match "type T is range <>;" (see 12.5.2).

*Examples**Examples of integer types and subtypes:*

```

33 type Page_Num is range 1 .. 2_000;
34 type Line_Size is range 1 .. Max_Line_Size;
35 subtype Small_Int is Integer range -10 .. 10;
36 subtype Column_Ptr is Line_Size range 1 .. 10;
37 subtype Buffer_Size is Integer range 0 .. Max;
38 type Byte is mod 256; -- an unsigned byte
39 type Hash_Index is mod 97; -- modulus is prime

```

*Extensions to Ada 83*

- 36.a An implementation is allowed to support any number of distinct base ranges for integer types, even if fewer integer types are explicitly declared in Standard.
- 36.b Modular (unsigned, wrap-around) types are new.

*Wording Changes from Ada 83*

- 36.c Ada 83's integer types are now called "signed" integer types, to contrast them with "modular" integer types.
- 36.d Standard.Integer, Standard.Long\_Integer, etc., denote constrained subtypes of predefined integer types, consistent with the Ada 95 model that only subtypes have names.
- 36.e We now impose minimum requirements on the base range of Integer and Long\_Integer.
- 36.f We no longer explain integer type definition in terms of an equivalence to a normal type derivation, except to say that all integer types are by definition implicitly derived from *root\_integer*. This is for various reasons.
- 36.g First of all, the equivalence with a type derivation and a subtype declaration was not perfect, and was the source of various AIs (for example, is the conversion of the bounds static? Is a numeric type a derived type with respect to other rules of the language?)
- 36.h Secondly, we don't want to require that every integer size supported shall have a corresponding named type in Standard. Adding named types to Standard creates nonportabilities.
- 36.i Thirdly, we don't want the set of types that match a formal derived type "type T is new Integer;" to depend on the particular underlying integer representation chosen to implement a given user-defined integer type. Hence, we would have needed anonymous integer types as parent types for the implicit derivation anyway. We have simply chosen to identify only one anonymous integer type — *root\_integer*, and stated that every integer type is derived from it.
- 36.j Finally, the "fiction" that there were distinct preexisting predefined types for every supported representation breaks down for fixed point with arbitrary smalls, and was never exploited for enumeration types, array types, etc. Hence, there seems little benefit to pushing an explicit equivalence between integer type definition and normal type derivation.

*Extensions to Ada 95*

{AI95-00340-01} The Mod attribute is new. It eases mixing of signed and unsigned values in an expression, which can be difficult as there may be no type which can contain all of the values of both of the types involved. 36.k/2

*Wording Changes from Ada 95*

{8652/0003} {AI95-00095-01} **Corrigendum:** Added additional permissions for modular types on one's complement machines. 36.l/2

### 3.5.5 Operations of Discrete Types

*Static Semantics*

- For every discrete subtype S, the following attributes are defined: 1
- S'Pos S'Pos denotes a function with the following specification: 2
- ```
function S'Pos (Arg : S'Base)
return universal_integer 3
```
- This function returns the position number of the value of *Arg*, as a value of type *universal_integer*. 4
- S'Val S'Val denotes a function with the following specification: 5
- ```
function S'Val (Arg : universal_integer)
return S'Base 6
```
- This function returns a value of the type of S whose position number equals the value of *Arg*. For the evaluation of a call on S'Val, if there is no value in the base range of its type with the given position number, Constraint\_Error is raised. 7
- Ramification:** By the overload resolution rules, a formal parameter of type *universal\_integer* allows an actual parameter of any integer type. 7.a
- Reason:** We considered allowing S'Val for a signed integer subtype S to return an out-of-range value, but since checks were required for enumeration and modular types anyway, the allowance didn't seem worth the complexity of the rule. 7.b
- {AI05-0297-1} For every static discrete subtype S for which there exists at least one value belonging to S that satisfies any predicate of S, the following attributes are defined: 7.1/3
- S'First\_Valid 7.2/3
- {AI05-0297-1} S'First\_Valid denotes the smallest value that belongs to S and satisfies the predicate of S. The value of this attribute is of the type of S.
- S'Last\_Valid 7.3/3
- {AI05-0297-1} S'Last\_Valid denotes the largest value that belongs to S and satisfies the predicate of S. The value of this attribute is of the type of S.
- {AI05-0297-1} [First\_Valid and Last\_Valid attribute\_references are always static expressions. Any explicit predicate of S can only have been specified by a Static\_Predicate aspect.] 7.4/3
- Proof:** An attribute\_reference is static if the prefix is a static subtype (see 4.9), (true by definition) and any arguments are static (there are none). Similarly, a dynamic predicate always makes a subtype nonstatic. QED. 7.c/3
- Reason:** We require there to be at least one value so that these are always values of the subtype. (This sidesteps the question of what to return for a subtype with no values.) 7.d/3
- Discussion:** These attributes are intended primarily for use in the case where the Static\_Predicate aspect of S has been specified; First and Last are equivalent if these are allowed and there is no predicate. 7.e/3

*Implementation Advice*

For the evaluation of a call on S'Pos for an enumeration subtype, if the value of the operand does not correspond to the internal code for any enumeration literal of its type [(perhaps due to an uninitialized variable)], then the implementation should raise Program\_Error. This is particularly important for 8

enumeration types with noncontiguous internal codes specified by an `enumeration_representation_clause`.

8.a.1/2 **Implementation Advice:** `Program_Error` should be raised for the evaluation of `S'Pos` for an enumeration type, if the value of the operand does not correspond to the internal code for any enumeration literal of the type.

8.a **Reason:** We say `Program_Error` here, rather than `Constraint_Error`, because the main reason for such values is uninitialized variables, and the normal way to indicate such a use (if detected) is to raise `Program_Error`. (Other reasons would involve the misuse of low-level features such as `Unchecked_Conversion`.)

#### NOTES

9 33 Indexing and loop iteration use values of discrete types.

10/3 34 *{AI05-0299-1}* The predefined operations of a discrete type include the assignment operation, qualification, the membership tests, and the relational operators; for a boolean type they include the short-circuit control forms and the logical operators; for an integer type they include type conversion to and from other numeric types, as well as the binary and unary adding operators `-` and `+`, the multiplying operators, the unary operator **abs**, and the exponentiation operator. The assignment operation is described in 5.2. The other predefined operations are described in Clause 4.

11 35 As for all types, objects of a discrete type have `Size` and `Address` attributes (see 13.3).

12 36 For a subtype of a discrete type, the result delivered by the attribute `Val` might not belong to the subtype; similarly, the actual parameter of the attribute `Pos` need not belong to the subtype. The following relations are satisfied (in the absence of an exception) by these attributes:

13 
$$\begin{aligned} S'Val(S'Pos(X)) &= X \\ S'Pos(S'Val(N)) &= N \end{aligned}$$

#### Examples

14 *Examples of attributes of discrete subtypes:*

15 *-- For the types and subtypes declared in subclause 3.5.1 the following hold:*

16 *-- Color'First = White, Color'Last = Black*  
 16 *-- Rainbow'First = Red, Rainbow'Last = Blue*

17 *-- Color'Succ(Blue) = Rainbow'Succ(Blue) = Brown*  
 17 *-- Color'Pos(Blue) = Rainbow'Pos(Blue) = 4*  
 17 *-- Color'Val(0) = Rainbow'Val(0) = White*

#### Extensions to Ada 83

17.a The attributes `S'Succ`, `S'Pred`, `S'Width`, `S'Image`, and `S'Value` have been generalized to apply to real types as well (see 3.5, “Scalar Types”).

#### Extensions to Ada 2005

17.b/3 *{AI05-0297-1}* The attributes `S'First_Valid` and `S'Last_Valid` are new.

## 3.5.6 Real Types

1 Real types provide approximations to the real numbers, with relative bounds on errors for floating point types, and with absolute bounds for fixed point types.

#### Syntax

2 `real_type_definition ::=`  
 2 `floating_point_definition | fixed_point_definition`

#### Static Semantics

3 A type defined by a `real_type_definition` is implicitly derived from `root_real`, an anonymous predefined (specific) real type. [Hence, all real types, whether floating point or fixed point, are in the derivation class rooted at `root_real`.]

3.a **Ramification:** It is not specified whether the derivation from `root_real` is direct or indirect, not that it really matters. All we want is for all real types to be descendants of `root_real`.

{8652/0099} {A195-00152-01} Note that this derivation does not imply any inheritance of subprograms. Subprograms are inherited only for types derived by a `derived_type_definition` (see 3.4), or a `private_extension_declaration` (see 7.3, 7.3.1, and 12.5.1). 3.a.1/1

[ Real literals are all of the type *universal\_real*, the universal type (see 3.4.1) for the class rooted at *root\_real*, allowing their use with the operations of any real type. Certain multiplying operators have a result type of *universal\_fixed* (see 4.5.5), the universal type for the class of fixed point types, allowing the result of the multiplication or division to be used where any specific fixed point type is expected.] 4

#### Dynamic Semantics

The elaboration of a `real_type_definition` consists of the elaboration of the `floating_point_definition` or the `fixed_point_definition`. 5

#### Implementation Requirements

An implementation shall perform the run-time evaluation of a use of a predefined operator of *root\_real* with an accuracy at least as great as that of any floating point type definable by a `floating_point_definition`. 6

**Ramification:** Static calculations using the operators of *root\_real* are exact, as for all static calculations. See 4.9. 6.a

**Implementation Note:** The Digits attribute of the type used to represent *root\_real* at run time is at least as great as that of any other floating point type defined by a `floating_point_definition`, and its safe range includes that of any such floating point type with the same Digits attribute. On some machines, there might be real types with less accuracy but a wider range, and hence run-time calculations with *root\_real* might not be able to accommodate all values that can be represented at run time in such floating point or fixed point types. 6.b

#### Implementation Permissions

{A195-00114-01} [For the execution of a predefined operation of a real type, the implementation need not raise `Constraint_Error` if the result is outside the base range of the type, so long as the correct result is produced, or the `Machine_Overflows` attribute of the type is `False` (see G.2).] 7/2

An implementation may provide *nonstandard real types*, descendants of *root\_real* that are declared outside of the specification of package `Standard`, which need not have all the standard characteristics of a type defined by a `real_type_definition`. For example, a nonstandard real type might have an asymmetric or unsigned base range, or its predefined operations might wrap around or “saturate” rather than overflow (modular or saturating arithmetic), or it might not conform to the accuracy model (see G.2). Any type descended from a nonstandard real type is also nonstandard. An implementation may place arbitrary restrictions on the use of such types; it is implementation defined whether operators that are predefined for “any real type” are defined for a particular nonstandard real type. [In any case, such types are not permitted as `explicit_generic_actual_parameters` for formal scalar types — see 12.5.2.] 8

**Implementation defined:** Any nonstandard real types and the operators defined for them. 8.a

#### NOTES

37 As stated, real literals are of the anonymous predefined real type *universal\_real*. Other real types have no literals. However, the overload resolution rules (see 8.6) allow expressions of the type *universal\_real* whenever a real type is expected. 9

#### Wording Changes from Ada 83

The syntax rule for `real_type_definition` is modified to use the new syntactic categories `floating_point_definition` and `fixed_point_definition`, instead of `floating_point_constraint` and `fixed_point_constraint`, because the semantics of a type definition are significantly different than the semantics of a constraint. 9.a

All discussion of model numbers, safe ranges, and machine numbers is moved to 3.5.7, 3.5.8, and G.2. Values of a fixed point type are now described as being multiples of the *small* of the fixed point type, and we have no need for model numbers, safe ranges, etc. for fixed point types. 9.b

### 3.5.7 Floating Point Types

- 1 For floating point types, the error bound is specified as a relative precision by giving the required minimum number of significant decimal digits.

*Syntax*

- ```
2 floating_point_definition ::=
   digits static_expression [real_range_specification]
3 real_range_specification ::=
   range static_simple_expression .. static_simple_expression
```

Name Resolution Rules

- 4 The *requested decimal precision*, which is the minimum number of significant decimal digits required for the floating point type, is specified by the value of the expression given after the reserved word **digits**. This expression is expected to be of any integer type.
- 5 Each `simple_expression` of a `real_range_specification` is expected to be of any real type[; the types need not be the same].

Legality Rules

- 6 The requested decimal precision shall be specified by a static expression whose value is positive and no greater than `System.Max_Base_Digits`. Each `simple_expression` of a `real_range_specification` shall also be static. If the `real_range_specification` is omitted, the requested decimal precision shall be no greater than `System.Max_Digits`.

- 6.a **Reason:** We have added `Max_Base_Digits` to package `System`. It corresponds to the requested decimal precision of *root_real*. `System.Max_Digits` corresponds to the maximum value for `Digits` that may be specified in the absence of a `real_range_specification`, for upward compatibility. These might not be the same if *root_real* has a base range that does not include $\pm 10.0^{*(4*\text{Max_Base_Digits})}$.

- 7 A `floating_point_definition` is illegal if the implementation does not support a floating point type that satisfies the requested decimal precision and range.

- 7.a **Implementation defined:** What combinations of requested decimal precision and range are supported for floating point types.

Static Semantics

- 8 The set of values for a floating point type is the (infinite) set of rational numbers. The *machine numbers* of a floating point type are the values of the type that can be represented exactly in every unconstrained variable of the type. The base range (see 3.5) of a floating point type is symmetric around zero, except that it can include some extra negative values in some implementations.

- 8.a **Implementation Note:** For example, if a 2's complement representation is used for the mantissa rather than a sign-mantissa or 1's complement representation, then there is usually one extra negative machine number.

- 8.b **To be honest:** If the `Signed_Zeros` attribute is `True`, then minus zero could in a sense be considered a value of the type. However, for most purposes, minus zero behaves the same as plus zero.

- 9 The *base decimal precision* of a floating point type is the number of decimal digits of precision representable in objects of the type. The *safe range* of a floating point type is that part of its base range for which the accuracy corresponding to the base decimal precision is preserved by all predefined operations.

- 9.a **Implementation Note:** In most cases, the safe range and base range are the same. However, for some hardware, values near the boundaries of the base range might result in excessive inaccuracies or spurious overflows when used with certain predefined operations. For such hardware, the safe range would omit such values.

A `floating_point_definition` defines a floating point type whose base decimal precision is no less than the requested decimal precision. If a `real_range_specification` is given, the safe range of the floating point type (and hence, also its base range) includes at least the values of the simple expressions given in the `real_range_specification`. If a `real_range_specification` is not given, the safe (and base) range of the type includes at least the values of the range $-10.0^{*(4*D)} .. +10.0^{*(4*D)}$ where D is the requested decimal precision. [The safe range might include other values as well. The attributes `Safe_First` and `Safe_Last` give the actual bounds of the safe range.] 10

A `floating_point_definition` also defines a first subtype of the type. If a `real_range_specification` is given, then the subtype is constrained to a range whose bounds are given by a conversion of the values of the simple expressions of the `real_range_specification` to the type being defined. Otherwise, the subtype is unconstrained. 11

To be honest: The conversion mentioned above is not an *implicit subtype conversion* (which is something that happens at overload resolution, see 4.6), although it happens implicitly. Therefore, the freezing rules are not invoked on the type (which is important so that representation items can be given for the type). 11.a.1/1

There is a predefined, unconstrained, floating point subtype named `Float`[, declared in the visible part of package `Standard`]. 12

Dynamic Semantics

[The elaboration of a `floating_point_definition` creates the floating point type and its first subtype.] 13

Implementation Requirements

In an implementation that supports floating point types with 6 or more digits of precision, the requested decimal precision for `Float` shall be at least 6. 14

If `Long_Float` is predefined for an implementation, then its requested decimal precision shall be at least 11. 15

Implementation Permissions

An implementation is allowed to provide additional predefined floating point types[, declared in the visible part of `Standard`], whose (unconstrained) first subtypes have names of the form `Short_Float`, `Long_Float`, `Short_Short_Float`, `Long_Long_Float`, etc. Different predefined floating point types are allowed to have the same base decimal precision. However, the precision of `Float` should be no greater than that of `Long_Float`. Similarly, the precision of `Short_Float` (if provided) should be no greater than `Float`. Corresponding recommendations apply to any other predefined floating point types. There need not be a named floating point type corresponding to each distinct base decimal precision supported by an implementation. 16

Implementation defined: The predefined floating point types declared in `Standard`. 16.a

Implementation Advice

An implementation should support `Long_Float` in addition to `Float` if the target machine supports 11 or more digits of precision. No other named floating point subtypes are recommended for package `Standard`. Instead, appropriate named floating point subtypes should be provided in the library package `Interfaces` (see B.2). 17

Implementation Advice: `Long_Float` should be declared in `Standard` if the target supports 11 or more digits of precision. No other named float subtypes should be declared in `Standard`. 17.a.1/2

Implementation Note: To promote portability, implementations should explicitly declare the floating point (sub)types `Float` and `Long_Float` in `Standard`, and leave other predefined float types anonymous. For implementations that already support `Short_Float`, etc., upward compatibility argues for keeping such declarations in `Standard` during the transition period, but perhaps generating a warning on use. A separate package `Interfaces` in the predefined environment is available for pre-declaring types such as `Float_32`, `IEEE_Float_64`, etc. See B.2. 17.a

NOTES

- 18 38 If a floating point subtype is unconstrained, then assignments to variables of the subtype involve only Overflow_Checks, never Range_Checks.

Examples

19 *Examples of floating point types and subtypes:*

```
20  type Coefficient is digits 10 range -1.0 .. 1.0;
21  type Real is digits 8;
   type Mass is digits 7 range 0.0 .. 1.0E35;
22  subtype Probability is Real range 0.0 .. 1.0;  -- a subtype with a smaller range
```

Inconsistencies With Ada 83

- 22.a No Range_Checks, only Overflow_Checks, are performed on variables (or parameters) of an unconstrained floating point subtype. This is upward compatible for programs that do not raise Constraint_Error. For those that do raise Constraint_Error, it is possible that the exception will be raised at a later point, or not at all, if extended range floating point registers are used to hold the value of the variable (or parameter).
- 22.b **Reason:** This change was felt to be justified by the possibility of improved performance on machines with extended-range floating point registers. An implementation need not take advantage of this relaxation in the range checking; it can hide completely the use of extended range registers if desired, presumably at some run-time expense.

Wording Changes from Ada 83

- 22.c The syntax rules for floating_point_constraint and floating_accuracy_definition are removed. The syntax rules for floating_point_definition and real_range_specification are new.
- 22.d A syntax rule for digits_constraint is given in 3.5.9, “Fixed Point Types”. In J.3 we indicate that a digits_constraint may be applied to a floating point subtype_mark as well (to be compatible with Ada 83's floating_point_constraint).
- 22.e Discussion of model numbers is postponed to 3.5.8 and G.2. The concept of safe numbers has been replaced by the concept of the safe range of values. The bounds of the safe range are given by T'Safe_First .. T'Safe_Last, rather than -T'Safe_Large .. T'Safe_Large, since on some machines the safe range is not perfectly symmetric. The concept of machine numbers is new, and is relevant to the definition of Succ and Pred for floating point numbers.

3.5.8 Operations of Floating Point Types

Static Semantics

1 The following attribute is defined for every floating point subtype S:

```
2/1 S'Digits    {8652/0004} {AI95-00203-01} S'Digits denotes the requested decimal precision for the
           subtype S. The value of this attribute is of the type universal_integer. The requested decimal
           precision of the base subtype of a floating point type T is defined to be the largest value of d
           for which
           ceiling(d * log(10) / log(T'Machine_Radix)) + g <= T'Model_Mantissa
           where g is 0 if Machine_Radix is a positive power of 10 and 1 otherwise.
```

NOTES

- 3 39 The predefined operations of a floating point type include the assignment operation, qualification, the membership tests, and explicit conversion to and from other numeric types. They also include the relational operators and the following predefined arithmetic operators: the binary and unary adding operators – and +, certain multiplying operators, the unary operator **abs**, and the exponentiation operator.
- 4 40 As for all types, objects of a floating point type have Size and Address attributes (see 13.3). Other attributes of floating point types are defined in A.5.3.

Wording Changes from Ada 95

4.a/2 {8652/0004} {AI95-00203-01} **Corrigendum:** Corrected the formula for Digits when the Machine_Radix is 10.

3.5.9 Fixed Point Types

A fixed point type is either an ordinary fixed point type, or a decimal fixed point type. The error bound of a fixed point type is specified as an absolute value, called the *delta* of the fixed point type.

Syntax

`fixed_point_definition ::= ordinary_fixed_point_definition | decimal_fixed_point_definition`

`ordinary_fixed_point_definition ::=`
`delta static expression real_range_specification`

`decimal_fixed_point_definition ::=`
`delta static expression digits static expression [real_range_specification]`

`digits_constraint ::=`
`digits static expression [range_constraint]`

Name Resolution Rules

For a type defined by a `fixed_point_definition`, the *delta* of the type is specified by the value of the expression given after the reserved word **delta**; this expression is expected to be of any real type. For a type defined by a `decimal_fixed_point_definition` (a *decimal* fixed point type), the number of significant decimal digits for its first subtype (the *digits* of the first subtype) is specified by the expression given after the reserved word **digits**; this expression is expected to be of any integer type.

Legality Rules

In a `fixed_point_definition` or `digits_constraint`, the expressions given after the reserved words **delta** and **digits** shall be static; their values shall be positive.

{AI95-00100-01} The set of values of a fixed point type comprise the integral multiples of a number called the *small* of the type. The *machine numbers* of a fixed point type are the values of the type that can be represented exactly in every unconstrained variable of the type. For a type defined by an `ordinary_fixed_point_definition` (an *ordinary* fixed point type), the *small* may be specified by an `attribute_definition_clause` (see 13.3); if so specified, it shall be no greater than the *delta* of the type. If not specified, the *small* of an ordinary fixed point type is an implementation-defined power of two less than or equal to the *delta*.

Implementation defined: The *small* of an ordinary fixed point type.

For a decimal fixed point type, the *small* equals the *delta*; the *delta* shall be a power of 10. If a `real_range_specification` is given, both bounds of the range shall be in the range $-(10^{**digits-1}) * delta .. +(10^{**digits-1}) * delta$.

A `fixed_point_definition` is illegal if the implementation does not support a fixed point type with the given *small* and specified range or *digits*.

Implementation defined: What combinations of *small*, range, and *digits* are supported for fixed point types.

For a `subtype_indication` with a `digits_constraint`, the `subtype_mark` shall denote a decimal fixed point subtype.

To be honest: Or, as an obsolescent feature, a floating point subtype is permitted — see J.3.

Static Semantics

The base range (see 3.5) of a fixed point type is symmetric around zero, except possibly for an extra negative value in some implementations.

13 An `ordinary_fixed_point_definition` defines an ordinary fixed point type whose base range includes at least all multiples of *small* that are between the bounds specified in the `real_range_specification`. The base range of the type does not necessarily include the specified bounds themselves. An `ordinary_fixed_point_definition` also defines a constrained first subtype of the type, with each bound of its range given by the closer to zero of:

- 14 • the value of the conversion to the fixed point type of the corresponding expression of the `real_range_specification`;

14.a.1/1 **To be honest:** The conversion mentioned above is not an *implicit subtype conversion* (which is something that happens at overload resolution, see 4.6), although it happens implicitly. Therefore, the freezing rules are not invoked on the type (which is important so that representation items can be given for the type).

- 15 • the corresponding bound of the base range.

16 A `decimal_fixed_point_definition` defines a decimal fixed point type whose base range includes at least the range $-(10^{**}digits-1)*delta .. +(10^{**}digits-1)*delta$. A `decimal_fixed_point_definition` also defines a constrained first subtype of the type. If a `real_range_specification` is given, the bounds of the first subtype are given by a conversion of the values of the expressions of the `real_range_specification`. Otherwise, the range of the first subtype is $-(10^{**}digits-1)*delta .. +(10^{**}digits-1)*delta$.

16.a.1/1 **To be honest:** The conversion mentioned above is not an *implicit subtype conversion* (which is something that happens at overload resolution, see 4.6), although it happens implicitly. Therefore, the freezing rules are not invoked on the type (which is important so that representation items can be given for the type).

Dynamic Semantics

17 The elaboration of a `fixed_point_definition` creates the fixed point type and its first subtype.

18 For a `digits_constraint` on a decimal fixed point subtype with a given *delta*, if it does not have a `range_constraint`, then it specifies an implicit range $-(10^{**}D-1)*delta .. +(10^{**}D-1)*delta$, where *D* is the value of the expression. A `digits_constraint` is *compatible* with a decimal fixed point subtype if the value of the expression is no greater than the *digits* of the subtype, and if it specifies (explicitly or implicitly) a range that is compatible with the subtype.

18.a **Discussion:** Except for the requirement that the *digits* specified be no greater than the *digits* of the subtype being constrained, a `digits_constraint` is essentially equivalent to a `range_constraint`.

18.b Consider the following example:

18.c `type D is delta 0.01 digits 7 range -0.00 .. 9999.99;`

18.d/1 The compatibility rule implies that the `digits_constraint` "`digits 6`" specifies an implicit range of "`-9999.99 .. 9999.99`". Thus, "`digits 6`" is not compatible with the constraint of `D`, but "`digits 6 range 0.00 .. 9999.99`" is compatible.

18.e/2 *{A195-00114-01}* A value of a scalar type belongs to a constrained subtype of the type if it belongs to the range of the subtype. Attributes like `Digits` and `Delta` have no effect on this fundamental rule. So the obsolescent forms of `digits_constraints` and `delta_constraints` that are called “accuracy constraints” in RM83 don't really represent constraints on the values of the subtype, but rather primarily affect compatibility of the “constraint” with the subtype being “constrained.” In this sense, they might better be called “subtype assertions” rather than “constraints.”

18.f Note that the `digits_constraint` on a decimal fixed point subtype is a combination of an assertion about the *digits* of the subtype being further constrained, and a constraint on the range of the subtype being defined, either explicit or implicit.

19 The elaboration of a `digits_constraint` consists of the elaboration of the `range_constraint`, if any. If a `range_constraint` is given, a check is made that the bounds of the range are both in the range $-(10^{**}D-1)*delta .. +(10^{**}D-1)*delta$, where *D* is the value of the (static) expression given after the reserved word `digits`. If this check fails, `Constraint_Error` is raised.

Implementation Requirements

20 The implementation shall support at least 24 bits of precision (including the sign bit) for fixed point types.

20.a **Reason:** This is sufficient to represent `Standard.Duration` with a *small* no more than 50 milliseconds.

Implementation Permissions

Implementations are permitted to support only *smalls* that are a power of two. In particular, all decimal fixed point type declarations can be disallowed. Note however that conformance with the Information Systems Annex requires support for decimal *smalls*, and decimal fixed point type declarations with *digits* up to at least 18. 21

Implementation Note: The accuracy requirements for multiplication, division, and conversion (see G.2.1, “Model of Floating Point Arithmetic”) are such that support for arbitrary *smalls* should be practical without undue implementation effort. Therefore, implementations should support fixed point types with arbitrary values for *small* (within reason). One reasonable limitation would be to limit support to fixed point types that can be converted to the most precise floating point type without loss of precision (so that `Fixed_IO` is implementable in terms of `Float_IO`). 21.a

NOTES

41 The base range of an ordinary fixed point type need not include the specified bounds themselves so that the range specification can be given in a natural way, such as: 22

```
type Fraction is delta 2.0**(-15) range -1.0 .. 1.0; 23
```

With 2's complement hardware, such a type could have a signed 16-bit representation, using 1 bit for the sign and 15 bits for fraction, resulting in a base range of $-1.0 .. 1.0 - 2.0^{-(15)}$. 24

Examples

Examples of fixed point types and subtypes: 25

```
type Volt is delta 0.125 range 0.0 .. 255.0; 26
```

```
-- A pure fraction which requires all the available 27
```

```
-- space in a word can be declared as the type Fraction:
```

```
type Fraction is delta System.Fine_Delta range -1.0 .. 1.0; 28
```

```
-- Fraction'Last = 1.0 - System.Fine_Delta
```

```
type Money is delta 0.01 digits 15; -- decimal fixed point 28
```

```
subtype Salary is Money digits 10;
```

```
-- Money'Last = 10.0**13 - 0.01, Salary'Last = 10.0**8 - 0.01
```

Inconsistencies With Ada 83

In Ada 95, `S'Small` always equals `S'Base'Small`, so if an implementation chooses a *small* for a fixed point type smaller than required by the *delta*, the value of `S'Small` in Ada 95 might not be the same as it was in Ada 83. 28.a

Extensions to Ada 83

{AI05-0005-1} Decimal fixed point types are new, though their capabilities are essentially similar to that available in Ada 83 with a fixed point type whose *small* equals its *delta* and both are a power of 10. However, in the Information Systems Annex, additional requirements are placed on the support of decimal fixed point types (e.g. a minimum of 18 digits of precision). 28.b/3

Wording Changes from Ada 83

The syntax rules for `fixed_point_constraint` and `fixed_accuracy_definition` are removed. The syntax rule for `fixed_point_definition` is new. A syntax rule for `delta_constraint` is included in the Obsolescent features (to be compatible with Ada 83's `fixed_point_constraint`). 28.c

Wording Changes from Ada 95

{AI95-00100-01} Added wording to define the machine numbers of fixed point types; this is needed by the static evaluation rules. 28.d/2

3.5.10 Operations of Fixed Point Types

Static Semantics

The following attributes are defined for every fixed point subtype `S`: 1

`S'Small` {8652/0005} {AI95-00054-01} `S'Small` denotes the *small* of the type of `S`. The value of this attribute is of the type *universal_real*. `Small` may be specified for nonderived ordinary fixed 2/1

point types via an `attribute_definition_clause` (see 13.3); the expression of such a clause shall be static.

2.a/3 **Aspect Description for Small:** Scale factor for a fixed point type.

3 S'Delta S'Delta denotes the *delta* of the fixed point subtype S. The value of this attribute is of the type *universal_real*.

3.a **Reason:** The *delta* is associated with the *subtype* as opposed to the *type*, because of the possibility of an (obsolescent) `delta_constraint`.

4 S'Fore S'Fore yields the minimum number of characters needed before the decimal point for the decimal representation of any value of the subtype S, assuming that the representation does not include an exponent, but includes a one-character prefix that is either a minus sign or a space. (This minimum number does not include superfluous zeros or underlines, and is at least 2.) The value of this attribute is of the type *universal_integer*.

5 S'Aft S'Aft yields the number of decimal digits needed after the decimal point to accommodate the *delta* of the subtype S, unless the *delta* of the subtype S is greater than 0.1, in which case the attribute yields the value one. [(S'Aft is the smallest positive integer N for which $(10^{**}N) * S'Delta$ is greater than or equal to one.)] The value of this attribute is of the type *universal_integer*.

6 The following additional attributes are defined for every decimal fixed point subtype S:

7 S'Digits S'Digits denotes the *digits* of the decimal fixed point subtype S, which corresponds to the number of decimal digits that are representable in objects of the subtype. The value of this attribute is of the type *universal_integer*. Its value is determined as follows:

- 8 • For a first subtype or a subtype defined by a `subtype_indication` with a `digits_constraint`, the *digits* is the value of the expression given after the reserved word **digits**;
- 9 • For a subtype defined by a `subtype_indication` without a `digits_constraint`, the *digits* of the subtype is the same as that of the subtype denoted by the `subtype_mark` in the `subtype_indication`.

9.a **Implementation Note:** Although a decimal subtype can be both range-constrained and digits-constrained, the `digits` constraint is intended to control the `Size` attribute of the subtype. For decimal types, `Size` can be important because input/output of decimal types is so common.

- 10 • The *digits* of a base subtype is the largest integer *D* such that the range $-(10^{**}D-1)*delta .. +(10^{**}D-1)*delta$ is included in the base range of the type.

11 S'Scale S'Scale denotes the *scale* of the subtype S, defined as the value N such that $S'Delta = 10.0^{**}(-N)$. [The *scale* indicates the position of the point relative to the rightmost significant digits of values of subtype S.] The value of this attribute is of the type *universal_integer*.

11.a **Ramification:** S'Scale is negative if S'Delta is greater than one. By contrast, S'Aft is always positive.

12 S'Round S'Round denotes a function with the following specification:

```
13     function S'Round (X : universal_real)
14     return S'Base
```

14 The function returns the value obtained by rounding X (away from 0, if X is midway between two values of the type of S).

NOTES

15 42 All subtypes of a fixed point type will have the same value for the `Delta` attribute, in the absence of `delta_constraints` (see J.3).

16 43 S'Scale is not always the same as S'Aft for a decimal subtype; for example, if S'Delta = 1.0 then S'Aft is 1 while S'Scale is 0.

17 44 The predefined operations of a fixed point type include the assignment operation, qualification, the membership tests, and explicit conversion to and from other numeric types. They also include the relational operators and the following

predefined arithmetic operators: the binary and unary adding operators – and +, multiplying operators, and the unary operator **abs**.

45 As for all types, objects of a fixed point type have Size and Address attributes (see 13.3). Other attributes of fixed point types are defined in A.5.4. 18

Wording Changes from Ada 95

{8652/0005} {AI95-00054-01} **Corrigendum:** Clarified that *small* may be specified only for ordinary fixed point types. 18.a/2

3.6 Array Types

An *array* object is a composite object consisting of components which all have the same subtype. The name for a component of an array uses one or more index values belonging to specified discrete types. The value of an array object is a composite value consisting of the values of the components. 1

Syntax

array_type_definition ::= 2

unconstrained_array_definition | constrained_array_definition

unconstrained_array_definition ::= 3

array(index_subtype_definition {, index_subtype_definition}) **of** component_definition

index_subtype_definition ::= subtype_mark **range** ◊ 4

constrained_array_definition ::= 5

array (discrete_subtype_definition {, discrete_subtype_definition}) **of** component_definition

discrete_subtype_definition ::= *discrete_subtype_indication* | range 6

{AI95-00230-01} {AI95-00406-01} component_definition ::= 7/2

[**aliased**] subtype_indication
| [**aliased**] access_definition

Name Resolution Rules

For a *discrete_subtype_definition* that is a range, the range shall resolve to be of some specific discrete type[; which discrete type shall be determined without using any context other than the bounds of the range itself (plus the preference for *root_integer* — see 8.6).] 8

Legality Rules

Each *index_subtype_definition* or *discrete_subtype_definition* in an *array_type_definition* defines an *index subtype*; its type (the *index type*) shall be discrete. 9

Discussion: An *index* is a discrete quantity used to select along a given dimension of an array. A component is selected by specifying corresponding values for each of the indices. 9.a

The subtype defined by the *subtype_indication* of a *component_definition* (the *component subtype*) shall be a definite subtype. 10

Ramification: This applies to all uses of *component_definition*, including in *record_type_definitions* and *protected_definitions*. 10.a

This paragraph was deleted. {AI95-00363-01} 11/2

Static Semantics

An array is characterized by the number of indices (the *dimensionality* of the array), the type and position of each index, the lower and upper bounds for each index, and the subtype of the components. The order of the indices is significant. 12

- 13 A one-dimensional array has a distinct component for each possible index value. A multidimensional array has a distinct component for each possible sequence of index values that can be formed by selecting one value for each index position (in the given order). The possible values for a given index are all the values between the lower and upper bounds, inclusive; this range of values is called the *index range*. The *bounds* of an array are the bounds of its index ranges. The *length* of a dimension of an array is the number of values of the index range of the dimension (zero for a null range). The *length* of a one-dimensional array is the length of its only dimension.
- 14 An *array_type_definition* defines an array type and its first subtype. For each object of this array type, the number of indices, the type and position of each index, and the subtype of the components are as in the type definition; the values of the lower and upper bounds for each index belong to the corresponding index subtype of its type, except for null arrays (see 3.6.1)].
- 15 An *unconstrained_array_definition* defines an array type with an unconstrained first subtype. Each *index_subtype_definition* defines the corresponding index subtype to be the subtype denoted by the *subtype_mark*. [The compound delimiter \diamond (called a *box*) of an *index_subtype_definition* stands for an undefined range (different objects of the type need not have the same bounds).]
- 16 A *constrained_array_definition* defines an array type with a constrained first subtype. Each *discrete_subtype_definition* defines the corresponding index subtype, as well as the corresponding index range for the constrained first subtype. The *constraint* of the first subtype consists of the bounds of the index ranges.
- 16.a/3 **Discussion:** {A105-0005-1} Although there is no nameable unconstrained array subtype in this case, the predefined slicing and concatenation operations can operate on and yield values that do not necessarily belong to the first array subtype. This is also true for Ada 83.
- 17 The discrete subtype defined by a *discrete_subtype_definition* is either that defined by the *subtype_indication*, or a subtype determined by the *range* as follows:
- 18 • If the type of the *range* resolves to *root_integer*, then the *discrete_subtype_definition* defines a subtype of the predefined type Integer with bounds given by a conversion to Integer of the bounds of the *range*;
- 18.a **Reason:** This ensures that indexing over the discrete subtype can be performed with regular Integers, rather than only *universal_integers*.
- 18.b **Discussion:** We considered doing this by simply creating a “preference” for Integer when resolving the *range*. However, this can introduce *Beaujolais* effects when the *simple_expressions* involve calls on functions visible due to *use* clauses.
- 19 • Otherwise, the *discrete_subtype_definition* defines a subtype of the type of the *range*, with the bounds given by the *range*.
- 20 The *component_definition* of an *array_type_definition* defines the nominal subtype of the components. If the reserved word **aliased** appears in the *component_definition*, then each component of the array is aliased (see 3.10).

Dynamic Semantics

- 21 The elaboration of an *array_type_definition* creates the array type and its first subtype, and consists of the elaboration of any *discrete_subtype_definitions* and the *component_definition*.
- 22/2 {8652/0002} {A195-00171-01} {A195-00230-01} The elaboration of a *discrete_subtype_definition* that does not contain any per-object expressions creates the discrete subtype, and consists of the elaboration of the *subtype_indication* or the evaluation of the *range*. The elaboration of a *discrete_subtype_definition* that contains one or more per-object expressions is defined in 3.8. The elaboration of a *component_definition* in an *array_type_definition* consists of the elaboration of the *subtype_indication* or

access_definition. The elaboration of any discrete_subtype_definitions and the elaboration of the component_definition are performed in an arbitrary order.

Static Semantics

{AI05-0228-1} For an array type with a scalar component type, the following language-defined representation aspect may be specified with an aspect_specification (see 13.1.1): 22.1/3

Default_Component_Value 22.2/3

This aspect shall be specified by a static expression, and that expression shall be explicit, even if the aspect has a boolean type. Default_Component_Value shall be specified only on a full_type_declaration.

Reason: The part about requiring an explicit expression is to disallow omitting the value for this aspect, which would otherwise be allowed by the rules of 13.1.1. 22.a/3

This is a representation attribute in order to disallow specifying it on a derived type that has inherited primitive subprograms; that is necessary as the sizes of **out** parameters could be different whether or not a Default_Value is specified (see 6.4.1). 22.b/3

Aspect Description for Default_Component_Value: Default value for the components of an array-of-scalar subtype. 22.c/3

{AI05-0228-1} If a derived type with no primitive subprograms inherits a boolean Default_Component_Value aspect, the aspect may be specified to have any value for the derived type. 22.3/3

Reason: This overrides the 13.1.1 rule that says that a boolean aspect with a value True cannot be changed. 22.d/3

Name Resolution Rules

{AI05-0228-1} The expected type for the expression specified for the Default_Component_Value aspect is the component type of the array type defined by the full_type_declaration on which it appears. 22.4/3

NOTES

46 All components of an array have the same subtype. In particular, for an array of components that are one-dimensional arrays, this means that all components have the same bounds and hence the same length. 23

47 Each elaboration of an array_type_definition creates a distinct array type. A consequence of this is that each object whose object_declaration contains an array_type_definition is of its own unique type. 24

Examples

Examples of type declarations with unconstrained array definitions: 25

```
type Vector      is array(Integer range <>) of Real;           26
type Matrix      is array(Integer range <>, Integer range <>) of Real;
type Bit_Vector is array(Integer range <>) of Boolean;
type Roman       is array(Positive range <>) of Roman_Digit; -- see 3.5.2
```

Examples of type declarations with constrained array definitions: 27

```
type Table       is array(1 .. 10) of Integer;                 28
type Schedule    is array(Day) of Boolean;
type Line        is array(1 .. Max_Line_Size) of Character;
```

Examples of object declarations with array type definitions: 29

```
{AI95-00433-01} Grid      : array(1 .. 80, 1 .. 100) of Boolean; 30/2
Mix      : array(Color range Red .. Green) of Boolean;
Msg_Table : constant array(Error_Code) of access constant String :=
  (Too_Big => new String'("Result too big"), Too_Small => ...);
Page     : array(Positive range <>) of Line := -- an array of arrays
  (1 | 50 => Line'(1 | Line'Last => '+', others => '-'), -- see 4.3.3
   2 .. 49 => Line'(1 | Line'Last => '|', others => ' '));
  -- Page is constrained by its initial value to (1..50)
```

Extensions to Ada 83

The syntax rule for component_definition is modified to allow the reserved word **aliased**. 30.a

30.b The syntax rules for `unconstrained_array_definition` and `constrained_array_definition` are modified to use `component_definition` (instead of `component_subtype_indication`). The effect of this change is to allow the reserved word **aliased** before the component subtype indication.

30.c A range in a `discrete_subtype_definition` may use arbitrary universal expressions for each bound (e.g. `-1 .. 3+5`), rather than strictly "implicitly convertible" operands. The subtype defined will still be a subtype of Integer.

Wording Changes from Ada 83

30.d We introduce a new syntactic category, `discrete_subtype_definition`, as distinct from `discrete_range`. These two constructs have the same syntax, but their semantics are quite different (one defines a subtype, with a preference for Integer subtypes, while the other just selects a subrange of an existing subtype). We use this new syntactic category in **for** loops and entry families.

30.e The syntax for `index_constraint` and `discrete_range` have been moved to their own subclause, since they are no longer used here.

30.f The syntax rule for `component_definition` (formerly `component_subtype_definition`) is moved here from RM83-3.7.

Extensions to Ada 95

30.g/2 *{AI95-00230-01}* *{AI95-00406-01}* Array components can have an anonymous access type.

30.h/2 *{AI95-00363-01}* The prohibition against unconstrained discriminated aliased components has been lifted. It has been replaced by a prohibition against the actual troublemakers: general access discriminant constraints (see 3.7.1).

Wording Changes from Ada 95

30.i/2 *{8652/0002}* *{AI95-00171-01}* **Corrigendum:** Added wording to allow the elaboration of per-object constraints for constrained arrays.

Extensions to Ada 2005

30.j/3 *{AI05-0228-1}* The new aspect `Default_Component_Value` allows defining implicit initial values (see 3.3.1) for arrays of scalar types.

3.6.1 Index Constraints and Discrete Ranges

1 An `index_constraint` determines the range of possible values for every index of an array subtype, and thereby the corresponding array bounds.

Syntax

2 `index_constraint ::= (discrete_range {, discrete_range})`

3 `discrete_range ::= discrete_subtype_indication | range`

Name Resolution Rules

4 The type of a `discrete_range` is the type of the subtype defined by the `subtype_indication`, or the type of the range. For an `index_constraint`, each `discrete_range` shall resolve to be of the type of the corresponding index.

4.a **Discussion:** In Ada 95, `index_constraints` only appear in a `subtype_indication`; they no longer appear in `constrained_array_definitions`.

Legality Rules

5 An `index_constraint` shall appear only in a `subtype_indication` whose `subtype_mark` denotes either an unconstrained array subtype, or an unconstrained access subtype whose designated subtype is an unconstrained array subtype; in either case, the `index_constraint` shall provide a `discrete_range` for each index of the array type.

Static Semantics

A `discrete_range` defines a range whose bounds are given by the `range`, or by the range of the subtype defined by the `subtype_indication`. 6

Dynamic Semantics

An `index_constraint` is *compatible* with an unconstrained array subtype if and only if the index range defined by each `discrete_range` is compatible (see 3.5) with the corresponding index subtype. If any of the `discrete_ranges` defines a null range, any array thus constrained is a *null array*, having no components. An array value *satisfies* an `index_constraint` if at each index position the array value and the `index_constraint` have the same index bounds. 7

Ramification: There is no need to define compatibility with a constrained array subtype, because one is not allowed to constrain it again. 7.a

The elaboration of an `index_constraint` consists of the evaluation of the `discrete_range(s)`, in an arbitrary order. The evaluation of a `discrete_range` consists of the elaboration of the `subtype_indication` or the evaluation of the `range`. 8

NOTES

48 The elaboration of a `subtype_indication` consisting of a `subtype_mark` followed by an `index_constraint` checks the compatibility of the `index_constraint` with the `subtype_mark` (see 3.2.2). 9

49 Even if an array value does not satisfy the index constraint of an array subtype, `Constraint_Error` is not raised on conversion to the array subtype, so long as the length of each dimension of the array value and the array subtype match. See 4.6. 10

Examples

Examples of array declarations including an index constraint: 11

```
Board      : Matrix(1 .. 8, 1 .. 8); -- see 3.6      12
Rectangle  : Matrix(1 .. 20, 1 .. 30);
Inverse    : Matrix(1 .. N, 1 .. N); -- N need not be static
Filter     : Bit_Vector(0 .. 31);                  13
```

Example of array declaration with a constrained array subtype: 14

```
My_Schedule : Schedule; -- all arrays of type Schedule have the same bounds 15
```

Example of record type with a component that is an array: 16

```
type Var_Line(Length : Natural) is
  record
    Image : String(1 .. Length);
  end record;

```

Extensions to Ada 83

We allow the declaration of a variable with a nominally unconstrained array subtype, so long as it has an initialization expression to determine its bounds. 18.a

Wording Changes from Ada 83

We have moved the syntax for `index_constraint` and `discrete_range` here since they are no longer used in `constrained_array_definitions`. We therefore also no longer have to describe the (special) semantics of `index_constraints` and `discrete_ranges` that appear in `constrained_array_definitions`. 18.b

The rules given in RM83-3.6.1(5,7-10), which define the bounds of an array object, are redundant with rules given elsewhere, and so are not repeated here. RM83-3.6.1(6), which requires that the (nominal) subtype of an array variable be constrained, no longer applies, so long as the variable is explicitly initialized. 18.c

3.6.2 Operations of Array Types

Legality Rules

- 1 [The argument `N` used in the `attribute_designators` for the `N`-th dimension of an array shall be a static expression of some integer type.] The value of `N` shall be positive (nonzero) and no greater than the dimensionality of the array.

Static Semantics

- 2/1 {8652/0006} {AI95-00030-01} The following attributes are defined for a prefix `A` that is of an array type [(after any implicit dereference)], or denotes a constrained array subtype:

- 2.a **Ramification:** These attributes are not defined if `A` is a subtype-mark for an access-to-array subtype. They are defined (by implicit dereference) for access-to-array values.

- 3 `A'First` `A'First` denotes the lower bound of the first index range; its type is the corresponding index type.

- 4 `A'First(N)` `A'First(N)` denotes the lower bound of the `N`-th index range; its type is the corresponding index type.

- 5 `A'Last` `A'Last` denotes the upper bound of the first index range; its type is the corresponding index type.

- 6 `A'Last(N)` `A'Last(N)` denotes the upper bound of the `N`-th index range; its type is the corresponding index type.

- 7 `A'Range` `A'Range` is equivalent to the range `A'First .. A'Last`, except that the prefix `A` is only evaluated once.

- 8 `A'Range(N)` `A'Range(N)` is equivalent to the range `A'First(N) .. A'Last(N)`, except that the prefix `A` is only evaluated once.

- 9 `A'Length` `A'Length` denotes the number of values of the first index range (zero for a null range); its type is *universal_integer*.

- 10 `A'Length(N)` `A'Length(N)` denotes the number of values of the `N`-th index range (zero for a null range); its type is *universal_integer*.

Implementation Advice

- 11/3 {AI05-0229-1} An implementation should normally represent multidimensional arrays in row-major order, consistent with the notation used for multidimensional array aggregates (see 4.3.3). However, if convention Fortran is specified for a multidimensional array type, then column-major order should be used instead (see B.5, “Interfacing with Fortran”).

- 11.a/2 **Implementation Advice:** Multidimensional arrays should be represented in row-major order, unless the array has convention Fortran.

NOTES

- 12 50 The `attribute_references` `A'First` and `A'First(1)` denote the same value. A similar relation exists for the `attribute_references` `A'Last`, `A'Range`, and `A'Length`. The following relation is satisfied (except for a null array) by the above attributes if the index type is an integer type:

$$13 \quad A'Length(N) = A'Last(N) - A'First(N) + 1$$

- 14 51 An array type is limited if its component type is limited (see 7.5).

- 15 52 The predefined operations of an array type include the membership tests, qualification, and explicit conversion. If the array type is not limited, they also include assignment and the predefined equality operators. For a one-dimensional array

type, they include the predefined concatenation operators (if nonlimited) and, if the component type is discrete, the predefined relational operators; if the component type is boolean, the predefined logical operators are also included.

53 {AI95-00287-01} A component of an array can be named with an `indexed_component`. A value of an array type can be specified with an `array_aggregate`. For a one-dimensional array type, a slice of the array can be named; also, string literals are defined if the component type is a character type. 16/2

Examples

Examples (using arrays declared in the examples of subclause 3.6.1): 17

```
-- Filter'First      = 0   Filter'Last      = 31   Filter'Length = 32   18
-- Rectangle'Last(1) = 20  Rectangle'Last(2) = 30
```

3.6.3 String Types

Static Semantics

A one-dimensional array type whose component type is a character type is called a *string* type. 1

{AI95-00285-01} [There are three predefined string types, `String`, `Wide_String`, and `Wide_Wide_String`, each indexed by values of the predefined subtype `Positive`; these are declared in the visible part of package `Standard`.] 2/2

```
[subtype Positive is Integer range 1 .. Integer'Last; 3
{AI95-00285-01} type String is array(Positive range <>) of Character; 4/2
type Wide_String is array(Positive range <>) of Wide_Character;
type Wide_Wide_String is array(Positive range <>) of Wide_Wide_Character;
]
```

NOTES

54 String literals (see 2.6 and 4.2) are defined for all string types. The concatenation operator `&` is predefined for string types, as for all nonlimited one-dimensional array types. The ordering operators `<`, `<=`, `>`, and `>=` are predefined for string types, as for all one-dimensional discrete array types; these ordering operators correspond to lexicographic order (see 4.5.2). 5

Examples

Examples of string objects: 6

```
Stars      : String(1 .. 120) := (1 .. 120 => '*' ); 7
Question   : constant String := "How many characters?";
              -- Question'First = 1, Question'Last = 20
              -- Question'Length = 20 (the number of characters)
Ask_Twice  : String := Question & Question;          -- constrained to (1..40) 8
Ninety_Six : constant Roman := "XCVI"; -- see 3.5.2 and 3.6
```

Inconsistencies With Ada 83

The declaration of `Wide_String` in `Standard` hides a use-visible declaration with the same `defining_identifier`. In rare cases, this might result in an inconsistency between Ada 83 and Ada 95. 8.a

Incompatibilities With Ada 83

Because both `String` and `Wide_String` are always directly visible, an expression like 8.b

```
"a" < "bc" 8.c
```

is now ambiguous, whereas in Ada 83 both string literals could be resolved to type `String`. 8.d

Extensions to Ada 83

The type `Wide_String` is new (though it was approved by ARG for Ada 83 compilers as well). 8.e

Wording Changes from Ada 83

We define the term *string type* as a natural analogy to the term *character type*. 8.f

Inconsistencies With Ada 95

- 8.g/2 {AI95-00285-01} The declaration of `Wide_Wide_String` in Standard hides a use-visible declaration with the same `defining_identifier`. In the (very) unlikely event that an Ada 95 program had depended on such a use-visible declaration, and the program remains legal after the substitution of `Standard.Wide_Wide_String`, the meaning of the program will be different.

Extensions to Ada 95

- 8.h/2 {AI95-00285-01} The type `Wide_Wide_String` is new.

3.7 Discriminants

- 1/2 {AI95-00251-01} {AI95-00326-01} [A composite type (other than an array or interface type) can have discriminants, which parameterize the type. A `known_discriminant_part` specifies the discriminants of a composite type. A discriminant of an object is a component of the object, and is either of a discrete type or an access type. An `unknown_discriminant_part` in the declaration of a view of a type specifies that the discriminants of the type are unknown for the given view; all subtypes of such a view are indefinite subtypes.]
- 1.a/2 **Glossary entry:** A discriminant is a parameter for a composite type. It can control, for example, the bounds of a component of the type if the component is an array. A discriminant for a task type can be used to pass data to a task of the type upon creation.
- 1.b/2 **Discussion:** {AI95-00114-01} A view of a type, and all subtypes of the view, have *unknown discriminants* when the number or names of the discriminants, if any, are unknown at the point of the type declaration for the view. A `discriminant_part` of ($\langle \rangle$) is used to indicate unknown discriminants.

Language Design Principles

- 1.c/2 {AI95-00402-01} When an access discriminant is initialized at the time of object creation with an allocator of an anonymous type, the allocated object and the object with the discriminant are tied together for their lifetime. They should be allocated out of the same storage pool, and then at the end of the lifetime of the enclosing object, finalized and reclaimed together. In this case, the allocated object is called a coextension (see 3.10.2).
- 1.d/2 **Discussion:** The above principle when applied to a nonlimited type implies that such an object may be copied only to a shorter-lived object, because attempting to assign it to a longer-lived object would fail because the access discriminants would not match. In a copy, the lifetime connection between the enclosing object and the allocated object does not exist. The allocated object is tied in the above sense only to the original object. Other copies have only secondary references to it.
- 1.e/2 Note that when an allocator appears as a constraint on an access discriminant in a `subtype_indication` that is elaborated independently from object creation, no such connection exists. For example, if a named constrained subtype is declared via "**subtype** Constr is Rec(Acc_Discrim => new T);" or if such an allocator appears in the `subtype_indication` for a component, the allocator is evaluated when the `subtype_indication` is elaborated, and hence its lifetime is typically longer than the objects or components that will later be subject to the constraint. In these cases, the allocated object should not be reclaimed until the `subtype_indication` goes out of scope.

Syntax

- 2 `discriminant_part ::= unknown_discriminant_part | known_discriminant_part`
- 3 `unknown_discriminant_part ::= ($\langle \rangle$)`
- 4 `known_discriminant_part ::=`
 `(discriminant_specification {; discriminant_specification})`
- 5/2 {AI95-00231-01} `discriminant_specification ::=`
 `defining_identifier_list : [null_exclusion] subtype_mark [:= default_expression]`
 `| defining_identifier_list : access_definition [:= default_expression]`
- 6 `default_expression ::= expression`

Name Resolution Rules

The expected type for the `default_expression` of a `discriminant_specification` is that of the corresponding discriminant. 7

Legality Rules

{8652/0007} {AI95-00098-01} {AI95-00251-01} A `discriminant_part` is only permitted in a declaration for a composite type that is not an array or interface type [(this includes generic formal types)]. A type declared with a `known_discriminant_part` is called a *discriminated* type, as is a type that inherits (known) discriminants. 8/2

Implementation Note: Discriminants on array types were considered, but were omitted to ease (existing) implementations. 8.a

Discussion: Note that the above definition for “discriminated type” does not include types declared with an `unknown_discriminant_part`. This seems consistent with Ada 83, where such types (in a generic formal part) would not be considered discriminated types. Furthermore, the full type for a type with unknown discriminants need not even be composite, much less have any discriminants. 8.b

{8652/0007} {AI95-00098-01} On the other hand, `unknown_discriminant_parts` cannot be applied to type declarations that cannot have a `known_discriminant_part`. There is no point in having unknown discriminants on a type that can never have discriminants (for instance, a formal modular type), even when these are allowed syntactically. 8.b.1/1

{AI95-00231-01} {AI95-00254-01} The subtype of a discriminant may be defined by an optional `null_exclusion` and a `subtype_mark`, in which case the `subtype_mark` shall denote a discrete or access subtype, or it may be defined by an `access_definition`. A discriminant that is defined by an `access_definition` is called an *access discriminant* and is of an anonymous access type. 9/2

This paragraph was deleted. {AI95-00230-01} 9.a/2

Reason: Note that discriminants of a named access type are not considered “access discriminants.” Similarly, “access parameter” only refers to a formal parameter defined by an `access_definition`. 9.b

{AI95-00402-01} {AI05-0214-1} `Default_expressions` shall be provided either for all or for none of the discriminants of a `known_discriminant_part`. No `default_expressions` are permitted in a `known_discriminant_part` in a declaration of a nonlimited tagged type [or a generic formal type]. 9.1/3

Reason: The all-or-none rule is related to the rule that a discriminant constraint shall specify values for all discriminants. One could imagine a different rule that allowed a constraint to specify only some of the discriminants, with the others provided by default. Having defaults for discriminants has a special significance — it allows objects of the type to be unconstrained, with the discriminants alterable as part of assigning to the object. 9.c/2

{AI05-0214-1} Defaults for discriminants of tagged types are disallowed so that every object of a nonlimited tagged type is constrained, either by an explicit constraint, or by its initial discriminant values. This substantially simplifies the semantic rules and the implementation of inherited dispatching operations. We don't need this rule for limited tagged types, as the discriminants of such objects cannot be changed after the object is created in any case — no full-object assignment is supported, and that is required to change discriminant values. For generic formal types, the restriction simplifies the type matching rules. If one simply wants a “default” value for the discriminants, a constrained subtype can be declared for future use. 9.d/3

{AI95-00230-01} {AI95-00402-01} {AI95-00419-01} {AI05-0063-1} A `discriminant_specification` for an access discriminant may have a `default_expression` only in the declaration for an immutably limited type (see 7.5). In addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit. 10/3

Discussion: This rule implies that a type can have a default for an access discriminant if the type is limited, but not if the only reason it's limited is because of a limited component. Compare the definition of limited type and immutably limited type in 7.5. 10.a/3

Ramification: A (nonformal) limited private type can always have a default for an access discriminant, because having the default itself makes the type immutably limited. Such a private type must necessarily have a full type with the same access discriminant with a default, and thus the full type will always be immutably limited (if legal). 10.b/3

- 10.c/2 **Reason:** {AI95-00230-01} We considered the following rules for access discriminants:
- 10.d • If a type has an access discriminant, this automatically makes it limited, just like having a limited component automatically makes a type limited. This was rejected because it decreases program readability, and because it seemed error prone (two bugs in a previous version of the RM9X were attributable to this rule).
- 10.e/2 • A type with an access discriminant shall be limited. This is equivalent to the rule we actually chose for Ada 95, except that it allows a type to have an access discriminant if it is limited just because of a limited component. For example, any record containing a task would be allowed to have an access discriminant, whereas the actual rule requires “**limited record**”. This rule was also rejected due to readability concerns, and because would interact badly with the rules for limited types that “become nonlimited”.
- 10.e.1/3 • {AI05-0063-1} A type may have an access discriminant if it is an immutably limited type. This was the rule chosen for Ada 95.
- 10.f/2 • Any type may have an access discriminant. For nonlimited type, there is no special accessibility for access discriminants; they're the same as any other anonymous access component. For a limited type, they have the special accessibility of Ada 95. However, this doesn't work because a limited partial view can have a nonlimited full view -- giving the two views different accessibility.
- 10.f.1/3 • {AI05-0063-1} Any type may have an access discriminant, as above. However, special accessibility rules only apply to types that are immutably limited (task, protected, and explicitly limited records). However, this breaks privacy; worse, Legality Rules depend on the definition of accessibility.
- 10.f.2/3 • {AI05-0063-1} Any type may have an access discriminant, as above. Limited types have special accessibility, while nonlimited types have normal accessibility. However, a limited partial view with an access discriminant can only be completed by an immutably limited type. That prevents accessibility from changing. A runtime accessibility check is required on generic formal types with access discriminants. However, changing between limited and nonlimited types would have far-reaching consequences for access discriminants — which is uncomfortable.
- 10.g/2 • Any type may have an access discriminant. All types have special accessibility. This was considered early during the Ada 9X process, but was dropped for “unpleasant complexities”, which unfortunately aren't recorded. It does seem that an accessibility check would be needed on assignment of such a type, to avoid copying an object with a discriminant pointing to a local object into a more global object (and thus creating a dangling pointer).
- 10.h/2 • Any type may have an access discriminant, but access discriminants cannot have defaults. All types have special accessibility. This gets rid of the problems on assignment (you couldn't change such a discriminant), but it would be horribly incompatible with Ada 95.
- 10.h.1/3 • {AI05-0063-1} Any type may have an access discriminant, but access discriminants may have defaults only if they are of an immutably limited type. This is the rule chosen for Ada 2005, as it is not incompatible, and it doesn't require weird accessibility checks.
- 11/2 *This paragraph was deleted.* {AI95-00402-01}
- 12 For a type defined by a `derived_type_definition`, if a `known_discriminant_part` is provided in its declaration, then:
- 13 • The parent subtype shall be constrained;
- 14 • If the parent type is not a tagged type, then each discriminant of the derived type shall be used in the constraint defining the parent subtype;
- 14.a **Implementation Note:** This ensures that the new discriminant can share storage with an existing discriminant.
- 15 • If a discriminant is used in the constraint defining the parent subtype, the subtype of the discriminant shall be statically compatible (see 4.9.1) with the subtype of the corresponding parent discriminant.
- 15.a **Reason:** This ensures that on conversion (or extension via an extension aggregate) to a distantly related type, if the discriminants satisfy the target type's requirements they satisfy all the intermediate types' requirements as well.
- 15.b **Ramification:** There is no requirement that the new discriminant have the same (or any) `default_expression` as the parent's discriminant.
- 16/3 *This paragraph was deleted.* {AI05-0102-1}
- 16.a/3 *This paragraph was deleted.*

Static Semantics

A `discriminant_specification` declares a discriminant; the `subtype_mark` denotes its subtype unless it is an access discriminant, in which case the discriminant's subtype is the anonymous access-to-variable subtype defined by the `access_definition`. 17

[For a type defined by a `derived_type_definition`, each discriminant of the parent type is either inherited, constrained to equal some new discriminant of the derived type, or constrained to the value of an expression.] When inherited or constrained to equal some new discriminant, the parent discriminant and the discriminant of the derived type are said to *correspond*. Two discriminants also correspond if there is some common discriminant to which they both correspond. A discriminant corresponds to itself as well. If a discriminant of a parent type is constrained to a specific value by a `derived_type_definition`, then that discriminant is said to be *specified* by that `derived_type_definition`. 18

Ramification: The correspondence relationship is transitive, symmetric, and reflexive. That is, if A corresponds to B, and B corresponds to C, then A, B, and C each corresponds to A, B, and C in all combinations. 18.a

A constraint that appears within the definition of a discriminated type *depends on a discriminant* of the type if it names the discriminant as a bound or discriminant value. A `component_definition` depends on a discriminant if its constraint depends on the discriminant, or on a discriminant that corresponds to it. 19

Ramification: A constraint in a `task_body` is not considered to *depend* on a discriminant of the task type, even if it names it. It is only the constraints in the type definition itself that are considered dependents. Similarly for protected types. 19.a

A component *depends on a discriminant* if: 20

- Its `component_definition` depends on the discriminant; or 21

Ramification: A component does *not* depend on a discriminant just because its `default_expression` refers to the discriminant. 21.a

- It is declared in a `variant_part` that is governed by the discriminant; or 22

- It is a component inherited as part of a `derived_type_definition`, and the constraint of the `parent_subtype_indication` depends on the discriminant; or 23

Reason: When the parent subtype depends on a discriminant, the parent part of the derived type is treated like a discriminant-dependent component. 23.a

Ramification: Because of this rule, we don't really need to worry about “corresponding” discriminants, since all the inherited components will be discriminant-dependent if there is a new `known_discriminant_part` whose discriminants are used to constrain the old discriminants. 23.b

- It is a subcomponent of a component that depends on the discriminant. 24

Reason: The concept of discriminant-dependent (sub)components is primarily used in various rules that disallow renaming or 'Access, or specify that certain discriminant-changing assignments are erroneous. The goal is to allow implementations to move around or change the size of discriminant-dependent subcomponents upon a discriminant-changing assignment to an enclosing object. The above definition specifies that all subcomponents of a discriminant-dependent component or parent part are themselves discriminant-dependent, even though their presence or size does not in fact depend on a discriminant. This is because it is likely that they will move in a discriminant-changing assignment if they are a component of one of several discriminant-dependent parts of the same record. 24.a

Each value of a discriminated type includes a value for each component of the type that does not depend on a discriminant[; this includes the discriminants themselves]. The values of discriminants determine which other component values are present in the value of the discriminated type. 25

To be honest: Which values are present might depend on discriminants of some ancestor type that are constrained in an intervening `derived_type_definition`. That's why we say "values of discriminants" instead of "values of *the* discriminants" — a subtle point. 25.a

A type declared with a `known_discriminant_part` is said to have *known discriminants*; its first subtype is unconstrained. A type declared with an `unknown_discriminant_part` is said to have *unknown discriminants*. A type declared without a `discriminant_part` has no discriminants, unless it is a derived 26

type; if derived, such a type has the same sort of discriminants (known, unknown, or none) as its parent (or ancestor) type. A tagged class-wide type also has unknown discriminants. [Any subtype of a type with unknown discriminants is an unconstrained and indefinite subtype (see 3.2 and 3.3).]

- 26.a/2 **Discussion:** *{AI95-00114-01}* An `unknown_discriminant_part` “(\diamond)” is only permitted in the declaration of a (generic or nongeneric) private type, private extension, incomplete type, or formal derived type. Hence, only such types, descendants thereof, and class-wide types can have unknown discriminants. An `unknown_discriminant_part` is used to indicate that the corresponding actual or full type might have discriminants without defaults, or be an unconstrained array subtype. Tagged class-wide types are also considered to have unknown discriminants because discriminants can be added by type extensions, so the total number of discriminants of any given value of a tagged class-wide type is not known at compile time.
- 26.b/2 *{AI95-00287-01}* A subtype with unknown discriminants is indefinite, and hence an object of such a subtype needs explicit initialization. A limited private type with unknown discriminants is “extremely” limited; objects of such a type can be initialized only by subprograms (either procedures with a parameter of the type, or a function returning the type) declared in the package. Subprograms declared elsewhere can operate on and even return the type, but they can only initialize the object by calling (ultimately) a subprogram in the package declaring the type. Such a type is useful for keeping complete control over object creation within the package declaring the type.
- 26.c A partial view of a type might have unknown discriminants, while the full view of the same type might have known, unknown, or no discriminants.

Dynamic Semantics

- 27/2 *{AI95-00230-01}* *{AI95-00416-01}* For an access discriminant, its `access_definition` is elaborated when the value of the access discriminant is defined: by evaluation of its `default_expression`, by elaboration of a `discriminant_constraint`, or by an assignment that initializes the enclosing object.
- 27.a/2 **Ramification:** *{AI95-00231-01}* *{AI95-00416-01}* The conversion of the expression defining the access discriminant to the anonymous access type raises `Program_Error` for an object created by an allocator of an access type T, if the initial value is an access parameter that designates a view whose accessibility level is deeper than that of T.

NOTES

- 28 55 If a discriminated type has `default_expressions` for its discriminants, then unconstrained variables of the type are permitted, and the values of the discriminants can be changed by an assignment to such a variable. If defaults are not provided for the discriminants, then all variables of the type are constrained, either by explicit constraint or by their initial value; the values of the discriminants of such a variable cannot be changed after initialization.
- 28.a **Discussion:** This connection between discriminant defaults and unconstrained variables can be a source of confusion. For Ada 95, we considered various ways to break the connection between defaults and unconstrainedness, but ultimately gave up for lack of a sufficiently simple and intuitive alternative.
- 28.b An unconstrained discriminated subtype with defaults is called a *mutable* subtype, and a variable of such a subtype is called a mutable variable, because the discriminants of such a variable can change. There are no mutable arrays (that is, the bounds of an array object can never change), because there is no way in the language to define default values for the bounds. Similarly, there are no mutable class-wide subtypes, because there is no way to define the default tag, and defaults for discriminants are not allowed in the tagged case. Mutable tags would also require a way for the maximum possible size of such a class-wide subtype to be known. (In some implementations, all mutable variables are allocated with the maximum possible size. This approach is appropriate for real-time applications where implicit use of the heap is inappropriate.)
- 29 56 The `default_expression` for a discriminant of a type is evaluated when an object of an unconstrained subtype of the type is created.
- 30 57 Assignment to a discriminant of an object (after its initialization) is not allowed, since the name of a discriminant is a constant; neither `assignment_statements` nor assignments inherent in passing as an **in out** or **out** parameter are allowed. Note however that the value of a discriminant can be changed by assigning to the enclosing object, presuming it is an unconstrained variable.
- 30.a/2 **Discussion:** *{AI95-00114-01}* An `unknown_discriminant_part` is permitted only in the declaration of a private type (including generic formal private), private extension, incomplete type, or generic formal derived type. These are the things that will have a corresponding completion or generic actual, which will either define the discriminants, or say there are none. The (\diamond) indicates that the actual/full subtype might be an indefinite subtype. An `unknown_discriminant_part` is not permitted in a normal untagged derived type declaration, because there is no separate full type declaration for such a type. Note that (\diamond) allows unconstrained array bounds; those are somewhat like defaulted discriminants.
- 30.b For a derived type, either the discriminants are inherited as is, or completely respecified in a new `discriminant_part`. In this latter case, each discriminant of the parent type shall be constrained, either to a specific value, or to equal one of

the new discriminants. Constraining a parent type's discriminant to equal one of the new discriminants is like a renaming of the discriminant, except that the subtype of the new discriminant can be more restrictive than that of the parent's one. In any case, the new discriminant can share storage with the parent's discriminant.

58 A discriminant that is of a named access type is not called an access discriminant; that term is used only for discriminants defined by an `access_definition`. 31

*Examples**Examples of discriminated types:*

```

type Buffer(Size : Buffer_Size := 100) is           -- see 3.5.4
  record
    Pos    : Buffer_Size := 0;
    Value  : String(1 .. Size);
  end record;
type Matrix_Rec(Rows, Columns : Integer) is       34
  record
    Mat : Matrix(1 .. Rows, 1 .. Columns);         -- see 3.6
  end record;
type Square(Side : Integer) is new               35
  Matrix_Rec(Rows => Side, Columns => Side);
type Double_Square(Number : Integer) is         36
  record
    Left  : Square(Number);
    Right : Square(Number);
  end record;
{AI95-00433-01} {AI05-0229-1} task type Worker(Prio : System.Priority; Buf : access 37/3

```

Extensions to Ada 83

The syntax for a `discriminant_specification` is modified to allow an *access discriminant*, with a type specified by an `access_definition` (see 3.10). 37.a

{AI95-00251-01} Discriminants are allowed on all composite types other than array and interface types. 37.b/2

Discriminants may be of an access type. 37.c

Wording Changes from Ada 83

`Discriminant_parts` are not elaborated, though an `access_definition` is elaborated when the discriminant is initialized. 37.d

Extensions to Ada 95

{AI95-00230-01} {AI95-00402-01} {AI95-00416-01} Access discriminants (anonymous access types used as a discriminant) can be used on any type allowing discriminants. Defaults aren't allowed on discriminants of nonlimited types, however, so that accessibility problems don't happen on assignment. 37.e/2

{AI95-00231-01} `null_exclusion` can be used in the declaration of a discriminant. 37.f/2

Wording Changes from Ada 95

{8652/0007} {AI95-00098-01} **Corrigendum:** The wording was clarified so that types that cannot have discriminants cannot have an `unknown_discriminant_part`. 37.g/2

{AI95-00251-01} Added wording to prevent interfaces from having discriminants. We don't want interfaces to have any components. 37.h/2

{AI95-00254-01} Removed wording which implied or required an access discriminant to have an access-to-object type (anonymous access types can now be access-to-subprogram types as well). 37.i/2

{AI95-00326-01} {AI05-0299-1} Fixed the wording of the introduction to this subclause to reflect that both incomplete and partial views can have unknown discriminants. That was always true, but for some reason this wording specified partial views. 37.j/3

37.k/2 {AI95-00419-01} Changed the wording to use the new term “explicitly limited record”, which makes the intent much clearer (and eliminates confusion with derived types that happen to contain the reserved word **limited**).

Incompatibilities With Ada 2005

37.l/3 {AI05-0063-1} **Correction:** Changed the rules for when access discriminants can have defaults to depend on the new definition for immutably limited types; this will help ensure that unusual corner cases are properly handled. Note that the Ada 2005 rule was unintentionally incompatible with the Ada 95 rule (as enforced by the ACATS); this change brings it back into alignment with actual practice. So there should be no practical incompatibility.

Extensions to Ada 2005

37.m/3 {AI05-0214-1} A limited tagged type may now have defaults for its discriminants.

Wording Changes from Ada 2005

37.n/3 {AI05-0102-1} **Correction:** Moved implicit conversion Legality Rule to 8.6.

3.7.1 Discriminant Constraints

1 A `discriminant_constraint` specifies the values of the discriminants for a given discriminated type.

Language Design Principles

1.a/3 {AI05-0299-1} The rules in this subclause are intentionally parallel to those given in 4.3.1, “Record Aggregates”.

Syntax

2 `discriminant_constraint ::=`
 (`discriminant_association` {, `discriminant_association`})

3 `discriminant_association ::=`
 [`discriminant_selector_name` { | `discriminant_selector_name` } =>] `expression`

4 A `discriminant_association` is said to be *named* if it has one or more `discriminant_selector_names`; it is otherwise said to be *positional*. In a `discriminant_constraint`, any positional associations shall precede any named associations.

Name Resolution Rules

5 Each `selector_name` of a named `discriminant_association` shall resolve to denote a discriminant of the subtype being constrained; the discriminants so named are the *associated discriminants* of the named association. For a positional association, the *associated discriminant* is the one whose `discriminant_specification` occurred in the corresponding position in the `known_discriminant_part` that defined the discriminants of the subtype being constrained.

6 The expected type for the `expression` in a `discriminant_association` is that of the associated discriminant(s).

Legality Rules

7/3 {8652/0008} {AI95-00168-01} {AI95-00363-01} {AI05-0041-1} A `discriminant_constraint` is only allowed in a `subtype_indication` whose `subtype_mark` denotes either an unconstrained discriminated subtype, or an unconstrained access subtype whose designated subtype is an unconstrained discriminated subtype. However, in the case of an access subtype, a `discriminant_constraint` is legal only if any dereference of a value of the access type is known to be constrained (see 3.3). In addition to the places where Legality Rules normally apply (see 12.3), these rules apply also in the private part of an instance of a generic unit.

7.a.1/2 *This paragraph was deleted.* {8652/0008} {AI95-00168-01} {AI95-00363-01}

7.a/2 **Reason:** {AI95-00363-01} The second rule is necessary to prevent objects from changing so that they no longer match their constraint. In Ada 95, we attempted to prevent this by banning every case where an aliased object could be

- unconstrained or be changed by an enclosing assignment. New ways to cause this problem were being discovered frequently, meaning that new rules had to be dreamed up to cover them. Meanwhile, aliased objects and components were getting more and more limited. In Ada 2005, we sweep away all of that cruft and replace it by a simple rule “thou shalt not create an access subtype that can point to an item whose discriminants can be changed by assignment”.
- Discussion:** {AI05-0041-1} The second rule will only use the indefinite or dereference bullets in the definition of “known to be constrained”. The rule is worded in terms of “known to be constrained” in order to capture the special rules that apply in generic bodies (rather than repeating them and getting them subtly wrong). 7.b/3
- A named `discriminant_association` with more than one `selector_name` is allowed only if the named discriminants are all of the same type. A `discriminant_constraint` shall provide exactly one value for each discriminant of the subtype being constrained. 8
- This paragraph was deleted.* {AI05-0102-1} 9/3
- Ramification:** In addition, 8.6 requires that the `expression` associated with an access discriminant is convertible (see 4.6) to the anonymous access type. This implies both convertibility of designated types, and static accessibility. This implies that if an object of type T with an access discriminant is created by an allocator for an access type A, then it requires that the type of the `expression` associated with the access discriminant have an accessibility level that is not statically deeper than that of A. This is to avoid dangling references. 9.a/3
- Dynamic Semantics*
- A `discriminant_constraint` is *compatible* with an unconstrained discriminated subtype if each discriminant value belongs to the subtype of the corresponding discriminant. 10
- Ramification:** The "dependent compatibility check" has been eliminated in Ada 95. Any checking on subcomponents is performed when (and if) an object is created. 10.a
- Discussion:** There is no need to define compatibility with a constrained discriminated subtype, because one is not allowed to constrain it again. 10.b
- A composite value *satisfies* a discriminant constraint if and only if each discriminant of the composite value has the value imposed by the discriminant constraint. 11
- For the elaboration of a `discriminant_constraint`, the `expressions` in the `discriminant_associations` are evaluated in an arbitrary order and converted to the type of the associated discriminant (which might raise `Constraint_Error` — see 4.6); the `expression` of a named association is evaluated (and converted) once for each associated discriminant. The result of each evaluation and conversion is the value imposed by the constraint for the associated discriminant. 12
- Reason:** We convert to the type, not the subtype, so that the definition of compatibility of discriminant constraints is not vacuous. 12.a
- NOTES
- 59 The rules of the language ensure that a discriminant of an object always has a value, either from explicit or implicit initialization. 13
- Discussion:** Although it is illegal to constrain a class-wide tagged subtype, it is possible to have a partially constrained class-wide subtype: If the subtype S is defined by T(A => B), then S'Class is partially constrained in the sense that objects of subtype S'Class have to have discriminants corresponding to A equal to B, but there can be other discriminants defined in extensions that are not constrained to any particular value. 13.a
- Examples*
- {AI05-0299-1} *Examples (using types declared above in subclause 3.7):* 14/3
- ```

Large : Buffer(200); -- constrained, always 200 characters
 -- (explicit discriminant value)
Message : Buffer; -- unconstrained, initially 100 characters
 -- (default discriminant value)
Basis : Square(5); -- constrained, always 5 by 5
Illegal : Square; -- illegal, a Square has to be constrained

```
- 15

*Inconsistencies With Ada 83*

- 15.a Dependent compatibility checks are no longer performed on subtype declaration. Instead they are deferred until object creation (see 3.3.1). This is upward compatible for a program that does not raise `Constraint_Error`.

*Wording Changes from Ada 83*

- 15.b Everything in RM83-3.7.2(7-12), which specifies the initial values for discriminants, is now redundant with 3.3.1, 6.4.1, 8.5.1, and 12.4. Therefore, we don't repeat it here. Since the material is largely intuitive, but nevertheless complicated to state formally, it doesn't seem worth putting it in a "NOTE."

*Incompatibilities With Ada 95*

- 15.c/2 {8652/0008} {AI95-00168-01} {AI95-00363-01} The Corrigendum added a restriction on `discriminant_constraints` for general access subtypes. Such constraints are prohibited if the designated type can be treated as constrained somewhere in the program. Ada 2005 goes further and prohibits such `discriminant_constraints` if the designated type has (or might have, in the case of a formal type) defaults for its discriminants. The use of general access subtypes is rare, and this eliminates a boatload of problems that required many restrictions on the use of aliased objects and components (now lifted). Similarly, Ada 2005 prohibits `discriminant_constraints` on any access type whose designated type has a partial view that is constrained. Such a type will not be constrained in the heap to avoid privacy problems. Again, the use of such subtypes is rare (they can only happen within the package and its child units).

*Wording Changes from Ada 2005*

- 15.d/3 {AI05-0041-1} **Correction:** Revised the rules on access subtypes having discriminant constraints to depend on the "known to be constrained" rules. This centralizes the rules so that future fixes need to be made in only one place, as well as fixing bugs in obscure cases.
- 15.e/3 {AI05-0102-1} **Correction:** Moved implicit conversion Legality Rule to 8.6.

### 3.7.2 Operations of Discriminated Types

- 1 [If a discriminated type has `default_expressions` for its discriminants, then unconstrained variables of the type are permitted, and the discriminants of such a variable can be changed by assignment to the variable. For a formal parameter of such a type, an attribute is provided to determine whether the corresponding actual parameter is constrained or unconstrained.]

*Static Semantics*

- 2 For a prefix `A` that is of a discriminated type [(after any implicit dereference)], the following attribute is defined:

3/3 `A'Constrained`

{AI05-0214-1} Yields the value `True` if `A` denotes a constant, a value, a tagged object, or a constrained variable, and `False` otherwise.

- 3.a/3 **Implementation Note:** {AI05-0214-1} This attribute is primarily used on parameters, to determine whether the discriminants can be changed as part of an assignment. The `Constrained` attribute is statically `True` for `in` parameters. For `in out` and `out` parameters of a discriminated type, the value of this attribute needs to be passed as an implicit parameter, in general. However, if the type is tagged or does not have defaults for its discriminants, the attribute is statically `True`, so no implicit parameter is needed. Parameters of a limited untagged type with defaulted discriminants need this implicit parameter, unless there are no nonlimited views, because they might be passed to a subprogram whose body has visibility on a nonlimited view of the type, and hence might be able to assign to the object and change its discriminants.

- 3.b/3 **Reason:** {AI05-0214-1} All tagged objects are known to be constrained (as nonlimited tagged types cannot have discriminant defaults, and limited tagged objects are immutably limited), and are always considered constrained by this attribute to avoid distributed overhead for parameters of limited classwide types, as limited tagged objects may technically be unconstrained if they use defaulted discriminants. Such objects still cannot have their discriminants changed, as assignment is not supported for them, so there is no use for this attribute that would justify the overhead of passing it with all classwide parameters.

- 3.c/3 **Discussion:** {AI05-0005-1} {AI05-0214-1} If the type of `A` is a type derived from an untagged partial view of a tagged type such that it is not a tagged type, then `A` is not considered a tagged object, and `A'Constrained` can return either `True` or `False` depending on the nature of the object.

*Erroneous Execution*

The execution of a construct is erroneous if the construct has a constituent that is a name denoting a subcomponent that depends on discriminants, and the value of any of these discriminants is changed by this execution between evaluating the name and the last use (within this execution) of the subcomponent denoted by the name. 4

**Ramification:** This rule applies to `assignment_statements`, calls (except when the discriminant-dependent subcomponent is an `in` parameter passed by copy), `indexed_components`, and slices. Ada 83 only covered the first two cases. AI83-00585 pointed out the situation with the last two cases. The cases of `object_renaming_declarations` and generic formal `in out` objects are handled differently, by disallowing the situation at compile time. 4.a

*Extensions to Ada 83*

For consistency with other attributes, we are allowing the prefix of `Constrained` to be a value as well as an object of a discriminated type, and also an implicit dereference. These extensions are not important capabilities, but there seems no reason to make this attribute different from other similar attributes. We are curious what most Ada 83 compilers do with `F(1).X'Constrained`. 4.b/1

We now handle in a general way the cases of erroneous use identified by AI83-00585, where the prefix of an `indexed_component` or `slice` is discriminant-dependent, and the evaluation of the index or discrete range changes the value of a discriminant. 4.c

*Wording Changes from Ada 83*

We have moved all discussion of erroneous use of names that denote discriminant-dependent subcomponents to this subclause. In Ada 83, it used to appear separately under `assignment_statements` and subprogram calls. 4.d

*Wording Changes from Ada 2005*

{AI05-0214-1} `A'Constrained` is now defined to return `True` for any `A` that is a tagged object. This doesn't change the result for any `A` allowed by previous versions of Ada; the change is necessary to avoid unnecessary overhead for limited tagged parameters. 4.e/3

## 3.8 Record Types

A record object is a composite object consisting of named components. The value of a record object is a composite value consisting of the values of the components. 1

*Syntax*

`record_type_definition ::= [[abstract] tagged] [limited] record_definition` 2

`record_definition ::=` 3

```
record
 component_list
end record
| null record
```

`component_list ::=` 4

```
 component_item {component_item}
 | {component_item} variant_part
 | null;
```

{8652/0009} {AI95-00137-01} `component_item ::= component_declaration | aspect_clause` 5/1

{AI05-0183-1} `component_declaration ::=` 6/3

```
 defining_identifier_list : component_definition [:= default_expression]
 [aspect_specification];
```

## Name Resolution Rules

- 7 The expected type for the `default_expression`, if any, in a `component_declaration` is the type of the component.

## Legality Rules

- 8/2 *This paragraph was deleted.* {AI95-00287-01}
- 9/2 {AI95-00366-01} Each `component_declaration` declares a component of the record type. Besides components declared by `component_declarations`, the components of a record type include any components declared by `discriminant_specifications` of the record type declaration. [The identifiers of all components of a record type shall be distinct.]
- 9.a/3 **Proof:** {AI05-0299-1} The identifiers of all components of a record type have to be distinct because they are all declared immediately within the same declarative region. See Clause 8.
- 10 Within a `type_declaration`, a name that denotes a component, protected subprogram, or entry of the type is allowed only in the following cases:
- 11/3 • {AI05-0004-1} {AI05-0295-1} A name that denotes any component, protected subprogram, or entry is allowed within an `aspect_specification`, an operational item, or a representation item that occurs within the declaration of the composite type.
  - 12/3 • {AI05-0264-1} A name that denotes a noninherited discriminant is allowed within the declaration of the type, but not within the `discriminant_part`. If the discriminant is used to define the constraint of a component, the bounds of an entry family, or the constraint of the parent subtype in a `derived_type_definition`, then its name shall appear alone as a `direct_name` (not as part of a larger expression or expanded name). A discriminant shall not be used to define the constraint of a scalar component.
- 12.a **Reason:** The penultimate restriction simplifies implementation, and allows the outer discriminant and the inner discriminant or bound to possibly share storage.
- 12.b **Ramification:** Other rules prevent such a discriminant from being an inherited one.
- 12.c **Reason:** The last restriction is inherited from Ada 83. The restriction is not really necessary from a language design point of view, but we did not remove it, in order to avoid unnecessary changes to existing compilers.
- 12.d **Discussion:** Note that a discriminant can be used to define the constraint for a component that is of an access-to-composite type.
- 12.e/2 **Reason:** {AI95-00373-01} The above rules, and a similar one in 6.1 for formal parameters, are intended to allow initializations of components or parameters to occur in a (nearly) arbitrary order — whatever order is most efficient (subject to the restrictions of 3.3.1), since one `default_expression` cannot depend on the value of another one. They also prevent circularities.
- 12.f/3 **Ramification:** {AI05-0295-1} Inherited discriminants are not allowed to be denoted, except within `aspect_specifications` and representation items. However, the `discriminant_selector_name` of the parent `subtype_indication` is allowed to denote a discriminant of the parent.
- 13 If the name of the current instance of a type (see 8.6) is used to define the constraint of a component, then it shall appear as a `direct_name` that is the prefix of an `attribute_reference` whose result is of an access type, and the `attribute_reference` shall appear alone.
- 13.a **Reason:** This rule allows T'Access or T'Unchecked\_Access, but disallows, for example, a range constraint (1..T'Size). Allowing things like (1..T'Size) would mean that a per-object constraint could affect the size of the object, which would be bad.

## Static Semantics

- 13.1/3 {AI95-00318-02} {AI05-0004-1} If a `record_type_definition` includes the reserved word **limited**, the type is called an *explicitly limited record* type.

The `component_definition` of a `component_declaration` defines the (nominal) subtype of the component. If the reserved word **aliased** appears in the `component_definition`, then the component is aliased (see 3.10). 14

If the `component_list` of a record type is defined by the reserved word **null** and there are no discriminants, then the record type has no components and all records of the type are *null records*. A `record_definition` of **null record** is equivalent to **record null; end record**. 15

**Ramification:** This short-hand is available both for declaring a record type and a record extension — see 3.9.1. 15.a

#### *Dynamic Semantics*

The elaboration of a `record_type_definition` creates the record type and its first subtype, and consists of the elaboration of the `record_definition`. The elaboration of a `record_definition` consists of the elaboration of its `component_list`, if any. 16

The elaboration of a `component_list` consists of the elaboration of the `component_items` and `variant_part`, if any, in the order in which they appear. The elaboration of a `component_declaration` consists of the elaboration of the `component_definition`. 17

**Discussion:** If the `defining_identifier_list` has more than one `defining_identifier`, we presume here that the transformation explained in 3.3.1 has already taken place. Alternatively, we could say that the `component_definition` is elaborated once for each `defining_identifier` in the list. 17.a

{8652/0002} {AI95-00171-01} {AI95-00230-01} Within the definition of a composite type, if a `component_definition` or `discrete_subtype_definition` (see 9.5.2) includes a name that denotes a discriminant of the type, or that is an `attribute_reference` whose prefix denotes the current instance of the type, the expression containing the name is called a *per-object expression*, and the constraint or range being defined is called a *per-object constraint*. For the elaboration of a `component_definition` of a `component_declaration` or the `discrete_subtype_definition` of an `entry_declaration` for an entry family (see 9.5.2), if the component subtype is defined by an `access_definition` or if the constraint or range of the `subtype_indication` or `discrete_subtype_definition` is not a per-object constraint, then the `access_definition`, `subtype_indication`, or `discrete_subtype_definition` is elaborated. On the other hand, if the constraint or range is a per-object constraint, then the elaboration consists of the evaluation of any included expression that is not part of a per-object expression. Each such expression is evaluated once unless it is part of a named association in a discriminant constraint, in which case it is evaluated once for each associated discriminant. 18/2

{8652/0002} {AI95-00171-01} When a per-object constraint is elaborated [(as part of creating an object)], each per-object expression of the constraint is evaluated. For other expressions, the values determined during the elaboration of the `component_definition` or `entry_declaration` are used. Any checks associated with the enclosing `subtype_indication` or `discrete_subtype_definition` are performed[, including the subtype compatibility check (see 3.2.2),] and the associated subtype is created. 18.1/1

**Discussion:** The evaluation of other expressions that appear in `component_definitions` and `discrete_subtype_definitions` is performed when the type definition is elaborated. The evaluation of expressions that appear as `default_expressions` is postponed until an object is created. Expressions in representation items that appear within a composite type definition are evaluated according to the rules of the particular representation item. 18.a

#### NOTES

60 A `component_declaration` with several identifiers is equivalent to a sequence of single `component_declarations`, as explained in 3.3.1. 19

61 The `default_expression` of a record component is only evaluated upon the creation of a default-initialized object of the record type (presuming the object has the component, if it is in a `variant_part` — see 3.3.1). 20

62 The subtype defined by a `component_definition` (see 3.6) has to be a definite subtype. 21

63 If a record type does not have a `variant_part`, then the same components are present in all values of the type. 22

- 23 64 A record type is limited if it has the reserved word **limited** in its definition, or if any of its components are limited (see 7.5).
- 24 65 The predefined operations of a record type include membership tests, qualification, and explicit conversion. If the record type is nonlimited, they also include assignment and the predefined equality operators.
- 25/2 66 {AI95-00287-01} A component of a record can be named with a `selected_component`. A value of a record can be specified with a `record_aggregate`.

*Examples*

26 *Examples of record type declarations:*

```
27 type Date is
 record
 Day : Integer range 1 .. 31;
 Month : Month_Name;
 Year : Integer range 0 .. 4000;
 end record;
28 type Complex is
 record
 Re : Real := 0.0;
 Im : Real := 0.0;
 end record;
```

29 *Examples of record variables:*

```
30 Tomorrow, Yesterday : Date;
 A, B, C : Complex;
31 -- both components of A, B, and C are implicitly initialized to zero
```

*Extensions to Ada 83*

- 31.a The syntax rule for `component_declaration` is modified to use `component_definition` (instead of `component_subtype_definition`). The effect of this change is to allow the reserved word **aliased** before the `component_subtype_definition`.
- 31.b A short-hand is provided for defining a null record type (and a null record extension), as these will be more common for abstract root types (and derived types without additional components).
- 31.c The syntax rule for `record_type_definition` is modified to allow the reserved words **tagged** and **limited**. Tagging is new. Limitedness is now orthogonal to privateness. In Ada 83 the syntax implied that limited private was sort of more private than private. However, limitedness really has nothing to do with privateness; limitedness simply indicates the lack of assignment capabilities, and makes perfect sense for nonprivate types such as record types.

*Wording Changes from Ada 83*

- 31.d/1 {8652/0009} {AI95-00137-01} The syntax rules now allow `aspect_clauses` to appear in a `record_definition`. This is not a language extension, because Legality Rules prevent all language-defined representation clauses from appearing there. However, an implementation-defined `attribute_definition_clause` could appear there. The reason for this change is to allow the rules for `aspect_clauses` and representation pragmas to be as similar as possible.

*Extensions to Ada 95*

- 31.e/2 {AI95-00287-01} Record components can have an anonymous access type.
- 31.f/2 {AI95-00287-01} Limited components can be initialized, so long as the expression is one that allows building the object in place (such as an `aggregate` or `function_call`).

*Wording Changes from Ada 95*

- 31.g/2 {8652/0002} {AI95-00171-01} **Corrigendum:** Improved the description of the elaboration of per-object constraints.
- 31.h/2 {8652/0009} {AI95-00137-01} **Corrigendum:** Changed representation clauses to aspect clauses to reflect that they are used for more than just representation.
- 31.i/2 {AI95-00318-02} Defined *explicitly limited record* type to use in other rules.

*Extensions to Ada 2005*

- 31.j/3 {AI05-0183-1} An optional `aspect_specification` can be used in a `component_declaration`. This is described in 13.1.1.

### 3.8.1 Variant Parts and Discrete Choices

A record type with a `variant_part` specifies alternative lists of components. Each `variant` defines the components for the value or values of the discriminant covered by its `discrete_choice_list`. 1

**Discussion:** `Discrete_choice_lists` and `discrete_choices` are said to *cover* values as defined below; which `discrete_choice_list` covers a value determines which of various alternatives is chosen. These are used in `variant_parts`, `array_aggregates`, and `case_statements`. 1.a

#### *Language Design Principles*

The definition of “cover” in this subclause and the rules about discrete choices are designed so that they are also appropriate for array aggregates and case statements. 1.b

The rules of this subclause intentionally parallel those for case statements. 1.c

#### *Syntax*

```
variant_part ::= 2
 case discriminant_direct_name is
 variant
 {variant}
 end case;

variant ::= 3
 when discrete_choice_list =>
 component_list

discrete_choice_list ::= discrete_choice { | discrete_choice } 4
{AI05-0153-3} {AI05-0158-1} discrete_choice ::= 5/3
choice_expression | discrete_subtype_indication | range | others
```

#### *Name Resolution Rules*

The `discriminant_direct_name` shall resolve to denote a discriminant (called the *discriminant of the variant part*) specified in the `known_discriminant_part` of the `full_type_declaration` that contains the `variant_part`. The expected type for each `discrete_choice` in a `variant` is the type of the discriminant of the `variant_part`. 6

**Ramification:** A `full_type_declaration` with a `variant_part` has to have a (new) `known_discriminant_part`; the discriminant of the `variant_part` cannot be an inherited discriminant. 6.a

#### *Legality Rules*

The discriminant of the `variant_part` shall be of a discrete type. 7

**Ramification:** It shall not be of an access type, named or anonymous. 7.a

{AI05-0153-3} The `choice_expressions`, `subtype_indications`, and `ranges` given as `discrete_choices` in a `variant_part` shall be static. The `discrete_choice others` shall appear alone in a `discrete_choice_list`, and such a `discrete_choice_list`, if it appears, shall be the last one in the enclosing construct. 8/3

A `discrete_choice` is defined to *cover a value* in the following cases: 9

- {AI05-0262-1} A `discrete_choice` that is a `choice_expression` covers a value if the value equals the value of the `choice_expression` converted to the expected type. 10/3
- {AI05-0153-3} {AI05-0262-1} A `discrete_choice` that is a `subtype_indication` covers all values (possibly none) that belong to the subtype and that satisfy the static predicate of the subtype (see 3.2.4). 10.1/3

- 10.a/3 **Ramification:** {AI05-0262-1} A dynamic predicate is never allowed in this case (for `variants`, `case_statements`, and `case_expressions`, a subtype with a dynamic predicate isn't static and thus isn't allowed in a `discrete_choice`, and for a choice in an `array_aggregate`, a dynamic predicate is explicitly disallowed — see 3.2.4).
- 11/3 • {AI05-0153-3} A `discrete_choice` that is a `range` covers all values (possibly none) that belong to the range.
- 12 • The `discrete_choice others` covers all values of its expected type that are not covered by previous `discrete_choice_lists` of the same construct.
- 12.a **Ramification:** For `case_statements`, this includes values outside the range of the static subtype (if any) to be covered by the choices. It even includes values outside the base range of the case expression's type, since values of numeric types (and undefined values of any scalar type?) can be outside their base range.
- 13 A `discrete_choice_list` covers a value if one of its `discrete_choices` covers the value.
- 14 The possible values of the discriminant of a `variant_part` shall be covered as follows:
- 15/3 • {AI05-0153-3} {AI05-0188-1} {AI05-0262-1} If the discriminant is of a static constrained scalar subtype then, except within an instance of a generic unit, each non-**others** `discrete_choice` shall cover only values in that subtype that satisfy its predicate, and each value of that subtype that satisfies its predicate shall be covered by some `discrete_choice` [(either explicitly or by **others**)];
- 15.a/3 **Reason:** {AI05-0188-1} The exemption for a discriminated type declared in an instance allows the following example:
- 15.b/3
- ```

generic
  type T is new Integer;
package G is
  type Rec (Discrim : T) is record
    case Discrim is
      when -10 .. -1 =>
        Foo : Float;
      when others =>
        null;
    end case;
  end record;
end G;

```
- 15.c/3 `package I is new G (Natural); -- Legal`
- 16/3 • {AI05-0264-1} If the type of the discriminant is a descendant of a generic formal scalar type, then the `variant_part` shall have an **others** `discrete_choice`;
- 16.a **Reason:** The base range is not known statically in this case.
- 17 • Otherwise, each value of the base range of the type of the discriminant shall be covered [(either explicitly or by **others**)].
- 18 Two distinct `discrete_choices` of a `variant_part` shall not cover the same value.

Static Semantics

- 19 If the `component_list` of a `variant` is specified by **null**, the `variant` has no components.
- 20 The discriminant of a `variant_part` is said to *govern* the `variant_part` and its `variants`. In addition, the discriminant of a derived type governs a `variant_part` and its `variants` if it corresponds (see 3.7) to the discriminant of the `variant_part`.

Dynamic Semantics

- 21 A record value contains the values of the components of a particular `variant` only if the value of the discriminant governing the `variant` is covered by the `discrete_choice_list` of the `variant`. This rule applies in turn to any further `variant` that is, itself, included in the `component_list` of the given `variant`.
- 21.1/3 {AI05-0290-1} When an object of a discriminated type *T* is initialized by default, `Constraint_Error` is raised if no `discrete_choice_list` of any `variant` of a `variant_part` of *T* covers the value of the discriminant that governs the `variant_part`. When a `variant_part` appears in the `component_list` of another `variant` *V*,

this test is only applied if the value of the discriminant governing V is covered by the `discrete_choice_list` of V .

Implementation Note: This is not a “check”; it cannot be suppressed. However, in most cases it is not necessary to generate any code to raise this exception. A test is needed (and can fail) in the case where the discriminant subtype has a `Static_Predicate` specified, it also has predicate checking disabled, and the discriminant governs a `variant_part` which lacks a **when others** choice. 21.a/3

The test also could fail for a static discriminant subtype with range checking suppressed and the discriminant governs a `variant_part` which lacks a **when others** choice. But execution is erroneous if a range check that would have failed is suppressed (see 11.5), so an implementation does not have to generate code to check this case. (An unchecked failed predicate does not cause erroneous execution, so the test is required in that case.) 21.b/3

Like the checks associated with a per-object constraint, this test is not made during the elaboration of a `subtype_indication`. 21.c/3

The elaboration of a `variant_part` consists of the elaboration of the `component_list` of each variant in the order in which they appear. 22

Examples

Example of record type with a variant part: 23

```

type Device is (Printer, Disk, Drum); 24
type State is (Open, Closed);
type Peripheral(Unit : Device := Disk) is 25
  record
    Status : State;
    case Unit is
      when Printer =>
        Line_Count : Integer range 1 .. Page_Size;
      when others =>
        Cylinder : Cylinder_Index;
        Track : Track_Number;
    end case;
  end record;

```

Examples of record subtypes: 26

```

subtype Drum_Unit is Peripheral(Drum); 27
subtype Disk_Unit is Peripheral(Disk);

```

Examples of constrained record variables: 28

```

Writer : Peripheral(Unit => Printer); 29
Archive : Disk_Unit;

```

Extensions to Ada 83

In Ada 83, the discriminant of a `variant_part` is not allowed to be of a generic formal type. This restriction is removed in Ada 95; an **others discrete_choice** is required in this case. 29.a

Wording Changes from Ada 83

The syntactic category choice is removed. The syntax rules for `variant`, `array_aggregate`, and `case_statement` now use `discrete_choice_list` or `discrete_choice` instead. The syntax rule for `record_aggregate` now defines its own syntax for named associations. 29.b

{AI05-0299-1} We have added the term Discrete Choice to the title since this is where they are talked about. This is analogous to the name of the subclause "Index Constraints and Discrete Ranges" in the subclause on Array Types. 29.c/3

The rule requiring that the discriminant denote a discriminant of the type being defined seems to have been left implicit in RM83. 29.d

Incompatibilities With Ada 2005

{AI05-0158-1} Membership tests are no longer allowed as a `discrete_choice`, in order that those tests can be expanded to allow multiple tests in a single expression without ambiguity. Since a membership test has a boolean type, they are very unlikely to be used as a `discrete_choice`. 29.e/3

Extensions to Ada 2005

- 29.f/3 {AI05-0153-3} Subtypes with static predicates can be used in `discrete_choices`, and the coverage rules are modified to respect the predicates.
- 29.g/3 {AI05-0188-1} Variants in generic specifications are no longer rejected if the subtype of the actual type does not include all of the case choices. This probably isn't useful, but it is consistent with the treatment of `case_expressions`.

Wording Changes from Ada 2005

- 29.h/3 {AI05-0290-1} Added a test that some `variant` covers the value of a discriminant that governs a `variant_part`. This is similar to the test that some case limb covers the value of the `Selecting_expression` of a `case_statement`. This test cannot change the behavior of any nonerroneous Ada 2005 program, so it is not an inconsistency.

3.9 Tagged Types and Type Extensions

- 1 [Tagged types and type extensions support object-oriented programming, based on inheritance with extension and run-time polymorphism via *dispatching operations*.]

Language Design Principles

- 1.a/2 {AI95-00251-01} The intended implementation model is for the static portion of a tag to be represented as a pointer to a statically allocated and link-time initialized type descriptor. The type descriptor contains the address of the code for each primitive operation of the type. It probably also contains other information, such as might make membership tests convenient and efficient. Tags for nested type extensions must also have a dynamic part that identifies the particular elaboration of the type.
- 1.b The primitive operations of a tagged type are known at its first freezing point; the type descriptor is laid out at that point. It contains linker symbols for each primitive operation; the linker fills in the actual addresses.
- 1.b.1/2 {AI95-00251-01} Primitive operations of type extensions that are declared at a level deeper than the level of the ultimate ancestor from which they are derived can be represented by wrappers that use the dynamic part of the tag to call the actual primitive operation. The dynamic part would generally be some way to represent the static link or display necessary for making a nested call. One implementation strategy would be to store that information in the extension part of such nested type extensions, and use the dynamic part of the tag to point at it. (That way, the “dynamic” part of the tag could be static, at the cost of indirect access.)
- 1.b.2/2 {AI95-00251-01} If the tagged type is descended from any interface types, it also will need to include “subtags” (one for each interface) that describe the mapping of the primitive operations of the interface to the primitives of the type. These subtags could directly reference the primitive operations (for faster performance), or simply provide the tag “slot” numbers for the primitive operations (for easier derivation). In either case, the subtags would be used for calls that dispatch through a class-wide type of the interface.
- 1.c Other implementation models are possible.
- 1.d The rules ensure that “dangling dispatching” is impossible; that is, when a dispatching call is made, there is always a body to execute. This is different from some other object-oriented languages, such as Smalltalk, where it is possible to get a run-time error from a missing method.
- 1.e/2 {AI95-00251-01} Dispatching calls should be efficient, and should have a bounded worst-case execution time. This is important in a language intended for real-time applications. In the intended implementation model, a dispatching call involves calling indirect through the appropriate slot in the dispatch table. No complicated “method lookup” is involved although a call which is dispatching on an interface may require a lookup of the appropriate interface subtag.
- 1.f The programmer should have the choice at each call site of a dispatching operation whether to do a dispatching call or a statically determined call (i.e. whether the body executed should be determined at run time or at compile time).
- 1.g The same body should be executed for a call where the tag is statically determined to be TTag as for a dispatching call where the tag is found at run time to be TTag. This allows one to test a given tagged type with statically determined calls, with some confidence that run-time dispatching will produce the same behavior.
- 1.h All views of a type should share the same type descriptor and the same tag.
- 1.i The visibility rules determine what is legal at compile time; they have nothing to do with what bodies can be executed at run time. Thus, it is possible to dispatch to a subprogram whose declaration is not visible at the call site. In fact, this is one of the primary facts that gives object-oriented programming its power. The subprogram that ends up being dispatched to by a given call might even be designed long after the call site has been coded and compiled.
- 1.j Given that Ada has overloading, determining whether a given subprogram overrides another is based both on the names and the type profiles of the operations.

{AI95-00401-01} When a type extension is declared, if there is any place within its immediate scope where a certain subprogram of the parent or progenitor is visible, then a matching subprogram should override. If there is no such place, then a matching subprogram should be totally unrelated, and occupy a different slot in the type descriptor. This is important to preserve the privacy of private parts; when an operation declared in a private part is inherited, the inherited version can be overridden only in that private part, in the package body, and in any children of the package. 1.k/2

If an implementation shares code for instances of generic bodies, it should be allowed to share type descriptors of tagged types declared in the generic body, so long as they are not extensions of types declared in the specification of the generic unit. 1.1

Static Semantics

{AI95-00345-01} A record type or private type that has the reserved word **tagged** in its declaration is called a *tagged* type. In addition, an interface type is a tagged type, as is a task or protected type derived from an interface (see 3.9.4). [When deriving from a tagged type, as for any derived type, additional primitive subprograms may be defined, and inherited primitive subprograms may be overridden.] The derived type is called an *extension* of its ancestor types, or simply a *type extension*. 2/2

{AI95-00345-01} Every type extension is also a tagged type, and is a *record extension* or a *private extension* of some other tagged type, or a noninterface synchronized tagged type (see 3.9.4). A record extension is defined by a `derived_type_definition` with a `record_extension_part` (see 3.9.1)[, which may include the definition of additional components]. A private extension, which is a partial view of a record extension or of a synchronized tagged type, can be declared in the visible part of a package (see 7.3) or in a generic formal part (see 12.5.1). 2.1/2

Glossary entry: The objects of a tagged type have a run-time type tag, which indicates the specific type with which the object was originally created. An operand of a class-wide tagged type can be used in a dispatching call; the tag indicates which subprogram body to invoke. Nondispatching calls, in which the subprogram body to invoke is determined at compile time, are also allowed. Tagged types may be extended with additional components. 2.a

Ramification: {AI95-00218-03} If a tagged type is declared other than in a `package_specification`, it is impossible to add new primitive subprograms for that type, although it can inherit primitive subprograms, and those can be overridden. If the user incorrectly thinks a certain subprogram is primitive when it is not, and tries to call it with a dispatching call, an error message will be given at the call site. Similarly, by using an `overriding_indicator` (see 6.1), the user can declare that a subprogram is intended to be overriding, and get an error message when they made a mistake. The use of `overriding_indicators` is highly recommended in new code that does not need to be compatible with Ada 95. 2.b/2

An object of a tagged type has an associated (run-time) *tag* that identifies the specific tagged type used to create the object originally. [The tag of an operand of a class-wide tagged type *T*Class controls which subprogram body is to be executed when a primitive subprogram of type *T* is applied to the operand (see 3.9.2); using a tag to control which body to execute is called *dispatching*.] 3

{AI95-00344-01} The tag of a specific tagged type identifies the `full_type_declaration` of the type, and for a type extension, is sufficient to uniquely identify the type among all descendants of the same ancestor. If a declaration for a tagged type occurs within a `generic_package_declaration`, then the corresponding type declarations in distinct instances of the generic package are associated with distinct tags. For a tagged type that is local to a generic package body and with all of its ancestors (if any) also local to the generic body, the language does not specify whether repeated instantiations of the generic body result in distinct tags. 4/2

This paragraph was deleted. {AI95-00344-01} 4.a/2

Implementation Note: {AI95-00344-01} In most cases, a tag need only identify a particular tagged type declaration, and can therefore be a simple link-time-known address. However, for tag checks (see 3.9.2) it is essential that each descendant (that currently exists) of a given type have a unique tag. Hence, for types declared in shared generic bodies where an ancestor comes from outside the generic, or for types declared at a deeper level than an ancestor, the tag needs to be augmented with some kind of dynamic descriptor (which may be a static link, global display, instance descriptor pointer, or combination). This implies that type Tag may need to be two words, the second of which is normally null, but in these identified special cases needs to include a static link or equivalent. Within an object of one of these types with a two-word tag, the two parts of the tag would typically be separated, one part as the first word of the object, the second placed in the first extension part that corresponds to a type declared more nested than its parent 4.a.1/2

or declared in a shared generic body when the parent is declared outside. Alternatively, by using an extra level of indirection, the type `Tag` could remain a single-word.

4.b/2 {AI95-00344-01} For types that are not type extensions (even for ones declared in nested scopes), we do not require that repeated elaborations of the same `full_type_declaration` correspond to distinct tags. This was done so that Ada 2005 implementations of tagged types could maintain representation compatibility with Ada 95 implementations. Only type extensions that were not allowed in Ada 95 require additional information with the tag.

4.c/2 **To be honest:** {AI95-00344-01} The wording “is sufficient to uniquely identify the type among all descendants of the same ancestor” only applies to types that currently exist. It is not necessary to distinguish between descendants that currently exist, and descendants of the same type that no longer exist. For instance, the address of the stack frame of the subprogram that created the tag is sufficient to meet the requirements of this rule, even though it is possible, after the subprogram returns, that a later call of the subprogram could have the same stack frame and thus have an identical tag.

5 The following language-defined library package exists:

```
6/2 {AI95-00362-01} package Ada.Tags is
    pragma Preelaborate(Tags);
    type Tag is private;
    pragma Preelaborable_Initialization(Tag);
6.1/2 {AI95-00260-02} No_Tag : constant Tag;
7/2 {AI95-00400-01} function Expanded_Name(T : Tag) return String;
    function Wide_Expanded_Name(T : Tag) return Wide_String;
    function Wide_Wide_Expanded_Name(T : Tag) return Wide_Wide_String;
    function External_Tag(T : Tag) return String;
    function Internal_Tag(External : String) return Tag;
7.1/2 {AI95-00344-01} function Descendant_Tag(External : String; Ancestor : Tag)
return Tag;
    function Is_Descendant_At_Same_Level(Descendant, Ancestor : Tag)
    return Boolean;
7.2/2 {AI95-00260-02} function Parent_Tag (T : Tag) return Tag;
7.3/2 {AI95-00405-01} type Tag_Array is array (Positive range <>) of Tag;
7.4/2 {AI95-00405-01} function Interface_Ancestor_Tags (T : Tag) return Tag_Array;
7.5/3 {AI05-0173-1} function Is_Abstract (T : Tag) return Boolean;
8 Tag_Error : exception;
9 private
    ... -- not specified by the language
end Ada.Tags;
```

9.a **Reason:** `Tag` is a nonlimited, definite subtype, because it needs the equality operators, so that tag checking makes sense. Also, equality, assignment, and object declaration are all useful capabilities for this subtype.

9.b For an object `X` and a type `T`, “`X`Tag = TTag” is not needed, because a membership test can be used. However, comparing the tags of two objects cannot be done via membership. This is one reason to allow equality for type `Tag`.

9.1/2 {AI95-00260-02} `No_Tag` is the default initial value of type `Tag`.

9.c/2 **Reason:** {AI95-00260-02} This is similar to the requirement that all access values be initialized to `null`.

10/2 {AI95-00400-01} The function `Wide_Wide_Expanded_Name` returns the full expanded name of the first subtype of the specific type identified by the tag, in upper case, starting with a root library unit. The result is implementation defined if the type is declared within an unnamed `block_statement`.

10.a **To be honest:** This name, as well as each prefix of it, does not denote a `renaming_declaration`.

10.b/2 **Implementation defined:** The result of `Tags.Wide_Wide_Expanded_Name` for types declared within an unnamed `block_statement`.

10.1/2 {AI95-00400-01} The function `Expanded_Name` (respectively, `Wide_Expanded_Name`) returns the same sequence of graphic characters as that defined for `Wide_Wide_Expanded_Name`, if all the graphic characters are defined in `Character` (respectively, `Wide_Character`); otherwise, the sequence of characters is implementation defined, but no shorter than that returned by `Wide_Wide_Expanded_Name` for the same value of the argument.

- Implementation defined:** The sequence of characters of the value returned by `Tags.Expanded_Name` (respectively, `Tags.Wide_Expanded_Name`) when some of the graphic characters of `Tags.Wide_Wide_Expanded_Name` are not defined in `Character` (respectively, `Wide_Character`). 10.c/2
- The function `External_Tag` returns a string to be used in an external representation for the given tag. The call `External_Tag(S'Tag)` is equivalent to the `attribute_reference` `S'External_Tag` (see 13.3). 11
- Reason:** It might seem redundant to provide both the function `External_Tag` and the attribute `External_Tag`. The function is needed because the attribute can't be applied to values of type `Tag`. The attribute is needed so that it can be specified via an `attribute_definition_clause`. 11.a
- {AI95-00417-01} The string returned by the functions `Expanded_Name`, `Wide_Expanded_Name`, `Wide_Wide_Expanded_Name`, and `External_Tag` has lower bound 1. 11.1/2
- {AI95-00279-01} The function `Internal_Tag` returns a tag that corresponds to the given external tag, or raises `Tag_Error` if the given string is not the external tag for any specific type of the partition. `Tag_Error` is also raised if the specific type identified is a library-level type whose tag has not yet been created (see 13.14). 12/2
- Reason:** {AI95-00279-01} {AI05-0005-1} The check for uncreated library-level types prevents a reference to the type before execution reaches the freezing point of the type. This is important so that `T'Class'Input` or an instance of `Tags.Generic_Dispatching_Constructor` do not try to create an object of a type that hasn't been frozen (which might not have yet elaborated its constraints). We don't require this behavior for non-library-level types as the tag can be created multiple times and possibly multiple copies can exist at the same time, making the check complex. 12.a/3
- {AI95-00344-01} {AI05-0113-1} The function `Descendant_Tag` returns the (internal) tag for the type that corresponds to the given external tag and is both a descendant of the type identified by the `Ancestor` tag and has the same accessibility level as the identified ancestor. `Tag_Error` is raised if `External` is not the external tag for such a type. `Tag_Error` is also raised if the specific type identified is a library-level type whose tag has not yet been created, or if the given external tag identifies more than one type that has the appropriate `Ancestor` and accessibility level. 12.1/3
- Reason:** `Descendant_Tag` is used by `T'Class'Input` to identify the type identified by an external tag. Because there can be multiple elaborations of a given type declaration, `Internal_Tag` does not have enough information to choose a unique such type. `Descendant_Tag` does not return the tag for types declared at deeper accessibility levels than the ancestor because there could be ambiguity in the presence of recursion or multiple tasks. `Descendant_Tag` can be used in constructing a user-defined replacement for `T'Class'Input`. 12.b/2
- {AI05-0113-1} Rules for specifying external tags will usually prevent an external tag from identifying more than one type. However, an external tag can identify multiple types if a generic body contains a derivation of a tagged type declared outside of the generic, and there are multiple instances at the same accessibility level as the type. (The Standard allows default external tags to not be unique in this case.) 12.b.1/3
- {AI95-00344-01} The function `Is_Descendant_At_Same_Level` returns `True` if the `Descendant` tag identifies a type that is both a descendant of the type identified by `Ancestor` and at the same accessibility level. If not, it returns `False`. 12.2/2
- Reason:** `Is_Descendant_At_Same_Level` (or something similar to it) is used by `T'Class'Output` to determine whether the item being written is at the same accessibility level as `T`. It may be used to determine prior to using `T'Class'Output` whether `Tag_Error` will be raised, and also can be used in constructing a user-defined replacement for `T'Class'Output`. 12.c/2
- {AI05-0115-1} For the purposes of the dynamic semantics of functions `Descendant_Tag` and `Is_Descendant_At_Same_Level`, a tagged type `T2` is a *descendant* of a type `T1` if it is the same as `T1`, or if its parent type or one of its progenitor types is a descendant of type `T1` by this rule[, even if at the point of the declaration of `T2`, one of the derivations in the chain is not visible]. 12.3/3
- Discussion:** In other contexts, “descendant” is dependent on visibility, and the particular view a derived type has of its parent type. See 7.3.1. 12.c.1/3
- {AI95-00260-02} The function `Parent_Tag` returns the tag of the parent type of the type whose tag is `T`. If the type does not have a parent type (that is, it was not declared by a `derived_type_declaration`), then `No_Tag` is returned. 12.4/3

- 12.d/2 **Ramification:** The parent type is always the parent of the full type; a private extension appears to define a parent type, but it does not (only the various forms of derivation do that). As this is a run-time operation, ignoring privateness is OK.
- 12.5/3 *{AI95-00405-01}* The function `Interface_Anccestor_Tags` returns an array containing the tag of each interface ancestor type of the type whose tag is *T*, other than *T* itself. The lower bound of the returned array is 1, and the order of the returned tags is unspecified. Each tag appears in the result exactly once. [If the type whose tag is *T* has no interface ancestors, a null array is returned.]
- 12.e/2 **Ramification:** The result of `Interface_Anccestor_Tags` includes the tag of the parent type, if the parent is an interface.
- 12.f/2 Indirect interface ancestors are included in the result of `Interface_Anccestor_Tags`. That's because where an interface appears in the derivation tree has no effect on the semantics of the type; the only interesting property is whether the type has an interface as an ancestor.
- 12.6/3 *{AI05-0173-1}* The function `Is_Abstract` returns `True` if the type whose tag is *T* is abstract, and `False` otherwise.
- 13 For every subtype *S* of a tagged type *T* (specific or class-wide), the following attributes are defined:
- 14 S'Class S'Class denotes a subtype of the class-wide type (called *T*'Class in this International Standard) for the class rooted at *T* (or if *S* already denotes a class-wide subtype, then S'Class is the same as *S*).
- 15 S'Class is unconstrained. However, if *S* is constrained, then the values of S'Class are only those that when converted to the type *T* belong to *S*.
- 15.a **Ramification:** This attribute is defined for both specific and class-wide subtypes. The definition is such that S'Class'Class is the same as S'Class.
- 15.b Note that if *S* is constrained, S'Class is only partially constrained, since there might be additional discriminants added in descendants of *T* which are not constrained.
- 15.c/2 **Reason:** *{AI95-00326-01}* The Class attribute is not defined for untagged subtypes (except for incomplete types and private types whose full view is tagged — see J.11 and 7.3.1) so as to preclude implicit conversion in the absence of run-time type information. If it were defined for untagged subtypes, it would correspond to the concept of universal types provided for the predefined numeric classes.
- 16 S'Tag S'Tag denotes the tag of the type *T* (or if *T* is class-wide, the tag of the root type of the corresponding class). The value of this attribute is of type `Tag`.
- 16.a **Reason:** S'Class'Tag equals S'Tag, to avoid generic contract model problems when S'Class is the actual type associated with a generic formal derived type.
- 17 Given a prefix *X* that is of a class-wide tagged type [(after any implicit dereference)], the following attribute is defined:
- 18 X'Tag X'Tag denotes the tag of *X*. The value of this attribute is of type `Tag`.
- 18.a **Reason:** X'Tag is not defined if *X* is of a specific type. This is primarily to avoid confusion that might result about whether the `Tag` attribute should reflect the tag of the type of *X*, or the tag of *X*. No such confusion is possible if *X* is of a class-wide type.
- 18.1/2 *{AI95-00260-02}* *{AI95-00441-01}* The following language-defined generic function exists:
- 18.2/3 *{AI05-0229-1}* **generic**
 type *T* (<>) **is abstract tagged limited private;**
 type *Parameters* (<>) **is limited private;**
 with function `Constructor` (*Params* : **not null access** *Parameters*)
 return *T* **is abstract;**
function `Ada.Tags.Generic_Dispatching_Constructor`
 (*The_Tag* : `Tag`;
 Params : **not null access** *Parameters*) **return** *T*'Class
 with `Convention` => `Intrinsic`;
pragma `Preelaborate`(`Generic_Dispatching_Constructor`);

{AI95-00260-02} Tags.Generic_Dispatching_Constructor provides a mechanism to create an object of an appropriate type from just a tag value. The function Constructor is expected to create the object given a reference to an object of type Parameters. 18.3/2

Discussion: This specification is designed to make it easy to create dispatching constructors for streams; in particular, this can be used to construct overrides for T'Class'Input. 18.b/2

Note that any tagged type will match T (see 12.5.1). 18.c/2

Dynamic Semantics

The tag associated with an object of a tagged type is determined as follows: 19

- The tag of a stand-alone object, a component, or an aggregate of a specific tagged type *T* identifies *T*. 20

Discussion: The tag of a formal parameter of type *T* is not necessarily the tag of *T*, if, for example, the actual was a type conversion. 20.a

- The tag of an object created by an allocator for an access type with a specific designated tagged type *T*, identifies *T*. 21

Discussion: The tag of an object designated by a value of such an access type might not be *T*, if, for example, the access value is the result of a type conversion. 21.a

- The tag of an object of a class-wide tagged type is that of its initialization expression. 22

Ramification: The tag of an object (even a class-wide one) cannot be changed after it is initialized, since a “class-wide” assignment_statement raises Constraint_Error if the tags don't match, and a “specific” assignment_statement does not affect the tag. 22.a

- The tag of the result returned by a function whose result type is a specific tagged type *T* identifies *T*. 23

Implementation Note: *{AI95-00318-02}* For a limited tagged type, the return object is “built in place” in the ultimate result object with the appropriate tag. For a nonlimited type, a new anonymous object with the appropriate tag is created as part of the function return. See 6.5, “Return Statements”. 23.a/2

- *{AI95-00318-02}* The tag of the result returned by a function with a class-wide result type is that of the return object. 24/2

The tag is preserved by type conversion and by parameter passing. The tag of a value is the tag of the associated object (see 6.2). 25

{AI95-00260-02} *{AI95-00344-01}* *{AI95-00405-01}* *{AI05-0092-1}* *{AI05-0262-1}* Tag_Error is raised by a call of Descendant_Tag, Expanded_Name, External_Tag, Interface_Ancessor_Tags, Is_Abstract, Is_Descendant_At_Same_Level, Parent_Tag, Wide_Expanded_Name, or Wide_Wide_Expanded_Name if any tag passed is No_Tag. 25.1/3

{AI95-00260-02} An instance of Tags.Generic_Dispatching_Constructor raises Tag_Error if The_Tag does not represent a concrete descendant of T or if the innermost master (see 7.6.1) of this descendant is not also a master of the instance. Otherwise, it dispatches to the primitive function denoted by the formal Constructor for the type identified by The_Tag, passing Params, and returns the result. Any exception raised by the function is propagated. 25.2/2

Ramification: The tag check checks both that The_Tag is in T'Class, and that it is not abstract. These checks are similar to the ones required by streams for T'Class'Input (see 13.13.2). In addition, there is a check that the tag identifies a type declared on the current dynamic call chain, and not a more nested type or a type declared by another task. This check is not necessary for streams, because the stream attributes are declared at the same dynamic level as the type used. 25.a/2

Erroneous Execution

{AI95-00260-02} If an internal tag provided to an instance of Tags.Generic_Dispatching_Constructor or to any subprogram declared in package Tags identifies either a type that is not library-level and whose tag 25.3/2

has not been created (see 13.14), or a type that does not exist in the partition at the time of the call, then execution is erroneous.

- 25.b/2 **Ramification:** One reason that a type might not exist in the partition is that the tag refers to a type whose declaration was elaborated as part of an execution of a `subprogram_body` which has been left (see 7.6.1).
- 25.c/2 We exclude tags of library-level types from the current execution of the partition, because misuse of such tags should always be detected. `T'Tag` freezes the type (and thus creates the tag), and `Internal_Tag` and `Descendant_Tag` cannot return the tag of a library-level type that has not been created. All ancestors of a tagged type must be frozen no later than the (full) declaration of a type that uses them, so `Parent_Tag` and `Interface_Ancestors` cannot return a tag that has not been created. Finally, library-level types never cease to exist while the partition is executing. Thus, if the tag comes from a library-level type, there cannot be erroneous execution (the use of `Descendant_Tag` rather than `Internal_Tag` can help ensure that the tag is of a library-level type). This is also similar to the rules for `T'ClassInput` (see 13.13.2).
- 25.d/2 **Discussion:** *{AI95-00344-01}* Ada 95 allowed `Tag_Error` in this case, or expected the functions to work. This worked because most implementations used tags constructed at link-time, and each elaboration of the same `type_declaration` produced the same tag. However, Ada 2005 requires at least part of the tags to be dynamically constructed for a type derived from a type at a shallower level. For dynamically constructed tags, detecting the error can be expensive and unreliable. To see this, consider a program containing two tasks. Task A creates a nested tagged type, passes the tag to task B (which saves it), and then terminates. The nested tag (if dynamic) probably will need to refer in some way to the stack frame for task A. If task B later tries to use the tag created by task A, the tag's reference to the stack frame of A probably is a dangling pointer. Avoiding this would require some sort of protected tag manager, which would be a bottleneck in a program's performance. Moreover, we'd still have a race condition; if task A terminated after the tag check, but before the tag was used, we'd still have a problem. That means that all of these operations would have to be serialized. That could be a significant performance drain, whether or not nested tagged types are ever used. Therefore, we allow execution to become erroneous as we do for other dangling pointers. If the implementation can detect the error, we recommend that `Tag_Error` be raised.

Implementation Permissions

- 26/2 *{AI95-00260-02}* *{AI95-00279-01}* The implementation of `Internal_Tag` and `Descendant_Tag` may raise `Tag_Error` if no specific type corresponding to the string `External` passed as a parameter exists in the partition at the time the function is called, or if there is no such type whose innermost master is a master of the point of the function call.
- 26.a/2 **Reason:** *{AI95-00260-02}* *{AI95-00279-01}* *{AI95-00344-01}* Locking would be required to ensure that the mapping of strings to tags never returned tags of types which no longer exist, because types can cease to exist (because they belong to another task, as described above) during the execution of these operations. Moreover, even if these functions did use locking, that would not prevent the type from ceasing to exist at the instant that the function returned. Thus, we do not require the overhead of locking; hence the word “may” in this rule.

Implementation Advice

- 26.1/3 *{AI95-00260-02}* *{AI05-0113-1}* `Internal_Tag` should return the tag of a type, if one exists, whose innermost master is a master of the point of the function call.
- 26.b/3 **Implementation Advice:** `Tags.Internal_Tag` should return the tag of a type, if one exists, whose innermost master is a master of the point of the function call..
- 26.c/2 **Reason:** *{AI95-00260-02}* *{AI95-00344-01}* It's not helpful if `Internal_Tag` returns the tag of some type in another task when one is available in the task that made the call. We don't require this behavior (because it requires the same implementation techniques we decided not to insist on previously), but encourage it.
- 26.d/3 **Discussion:** *{AI05-0113-1}* There is no Advice for the result of `Internal_Tag` if no such type exists. In most cases, the Implementation Permission can be used to raise `Tag_Error`, but some other tag can be returned as well.

NOTES

- 27 A type declared with the reserved word **tagged** should normally be declared in a `package_specification`, so that new primitive subprograms can be declared for it.
- 28 68 Once an object has been created, its tag never changes.
- 29 69 Class-wide types are defined to have unknown discriminants (see 3.7). This means that objects of a class-wide type have to be explicitly initialized (whether created by an `object_declaration` or an `allocator`), and that aggregates have to be explicitly qualified with a specific type when their expected type is class-wide.

70 {AI95-00260-02} {AI95-00326-01} The capability provided by Tags.Generic_Dispatching_Constructor is sometimes known as a *factory*. 30/2

Examples

Examples of tagged record types:

```

type Point is tagged
  record
    X, Y : Real := 0.0;
  end record;
type Expression is tagged null record;
  -- Components will be added by each extension

```

31
32
33

Extensions to Ada 83

Tagged types are a new concept. 33.a

Inconsistencies With Ada 95

{AI95-00279-01} **Amendment Correction:** Added wording specifying that Internal_Tag must raise Tag_Error if the tag of a library-level type has not yet been created. Ada 95 gave an Implementation Permission to do this; we require it to avoid erroneous execution when streaming in an object of a library-level type that has not yet been elaborated. This is technically inconsistent; a program that used Internal_Tag outside of streaming and used a compiler that didn't take advantage of the Implementation Permission would not have raised Tag_Error, and may have returned a useful tag. (If the tag was used in streaming, the program would have been erroneous.) Since such a program would not have been portable to a compiler that did take advantage of the Implementation Permission, this is not a significant inconsistency. 33.b/2

{AI95-00417-01} We now define the lower bound of the string returned from [[Wide_]Wide_]Expanded_Name and External_Name. This makes working with the returned string easier, and is consistent with many other string-returning functions in Ada. This is technically an inconsistency; if a program depended on some other lower bound for the string returned from one of these functions, it could fail when compiled with Ada 2005. Such code is not portable even between Ada 95 implementations, so it should be very rare. 33.c/2

Incompatibilities With Ada 95

{AI95-00260-02} {AI95-00344-01} {AI95-00400-01} {AI95-00405-01} {AI05-0005-1} Constant No_Tag, and functions Parent_Tag, Interface_Anccestor_Tags, Descendant_Tag, Is_Descendant_At_Same_Level, Wide_Expanded_Name, and Wide_Wide_Expanded_Name are added to Ada.Tags. If Ada.Tags is referenced in a use_clause, and an entity *E* with the same defining_identifier as a new entity in Ada.Tags is defined in a package that is also referenced in a use_clause, the entity *E* may no longer be use-visible, resulting in errors. This should be rare and is easily fixed if it does occur. 33.d/3

Extensions to Ada 95

{AI95-00362-01} Ada.Tags is now defined to be preelaborated. 33.e/2

{AI95-00260-02} Generic function Tags.Generic_Dispatching_Constructor is new. 33.f/2

Wording Changes from Ada 95

{AI95-00318-02} We talk about return objects rather than return expressions, as functions can return using an extended_return_statement. 33.g/2

{AI95-00344-01} Added wording to define that tags for all descendants of a tagged type must be distinct. This is needed to ensure that more nested type extensions will work properly. The wording does not require implementation changes for types that were allowed in Ada 95. 33.h/2

Inconsistencies With Ada 2005

{AI05-0113-1} **Correction:** Added wording specifying that Dependent_Tag must raise Tag_Error if there is more than one type which matches the requirements. If an implementation had returned a random tag of the matching types, a program may have worked properly. However, such a program would not be portable (another implementation may return a different tag) and the conditions that would cause the problem are unlikely (most likely, a tagged type extension declared in a generic body with multiple instances in the same scope). 33.i/3

Incompatibilities With Ada 2005

- 33.j/3 {AI05-0173-1} Function `Is_Abstract` is added to `Ada.Tags`. If `Ada.Tags` is referenced in a `use_clause`, and an entity *E* with the `defining_identifier` `Is_Abstract` is defined in a package that is also referenced in a `use_clause`, the entity *E* may no longer be use-visible, resulting in errors. This should be rare and is easily fixed if it does occur.

Wording Changes from Ada 2005

- 33.k/3 {AI05-0115-1} **Correction:** We explicitly define the meaning of "descendant" at runtime, so that it does not depend on visibility as does the usual meaning.

3.9.1 Type Extensions

- 1/2 {AI95-00345-01} [Every type extension is a tagged type, and is a *record extension* or a *private extension* of some other tagged type, or a noninterface synchronized tagged type.]

Language Design Principles

- 1.a We want to make sure that we can extend a generic formal tagged type, without knowing its discriminants.
- 1.b We don't want to allow components in an extension aggregate to depend on discriminants inherited from the parent value, since such dependence requires staticness in aggregates, at least for variants.

Syntax

- 2 `record_extension_part ::= with record_definition`

Legality Rules

- 3/2 {AI95-00344-01} {AI95-00345-01} {AI95-00419-01} The parent type of a record extension shall not be a class-wide type nor shall it be a synchronized tagged type (see 3.9.4). If the parent type or any progenitor is nonlimited, then each of the components of the `record_extension_part` shall be nonlimited. In addition to the places where Legality Rules normally apply (see 12.3), these rules apply also in the private part of an instance of a generic unit.
- 3.a **Reason:** If the parent is a limited formal type, then the actual might be nonlimited.
- 3.b/2 {AI95-00344-01} Ada 95 required the record extensions to be the same level as the parent type. Now we use accessibility checks on class-wide allocators and return statements to prevent objects from living longer than their type.
- 3.c/2 {AI95-00345-01} Synchronized tagged types cannot be extended. We have this limitation so that all of the data of a task or protected type is defined within the type. Data defined outside of the type wouldn't be subject to the mutual exclusion properties of a protected type, and couldn't be used by a task, and thus doesn't seem to be worth the potential impact on implementations.
- 4/2 {AI95-00344-01} Within the body of a generic unit, or the body of any of its descendant library units, a tagged type shall not be declared as a descendant of a formal type declared within the formal part of the generic unit.
- 4.a **Reason:** This paragraph ensures that a dispatching call will never attempt to execute an inaccessible subprogram body.
- 4.a.1/2 {AI95-00344-01} The convoluted wording ("formal type declared within the formal part") is necessary to include tagged types that are formal parameters of formal packages of the generic unit, as well as formal tagged and tagged formal derived types of the generic unit.
- 4.b/2 {AI95-00344-01} This rule is necessary in order to preserve the contract model.
- 4.c/2 {AI05-0005-1} {AI95-00344-01} If an ancestor is a formal of the generic unit, we have a problem because it might have an unknown number of subprograms that require overriding, as in the following example:
- 4.d/2
- ```

package P is
 type T is tagged null record;
 function F return T; -- Inherited versions will require overriding.
end P;
```

```

generic
 type TT is tagged private;
package Gp is
 type NT is abstract new TT with null record;
 procedure Q(X : in NT) is abstract;
end Gp;

package body Gp is
 type NT2 is new NT with null record; -- Illegal!
 procedure Q(X : in NT2) is begin null; end Q;
 -- Is this legal or not? Can't decide because
 -- we don't know whether TT had any functions that require
 -- overriding on extension.
end Gp;

package I is new Gp(TT => P.T);

```

I.NT is an abstract type with two abstract subprograms: F (inherited as abstract) and Q (explicitly declared as abstract). But the generic body doesn't know about F, so we don't know that it needs to be overridden to make a nonabstract extension of NT. Hence, we have to disallow this case.

Similarly, since the actual type for a formal tagged limited private type can be a nonlimited type, we would have a problem if a type extension of a limited private formal type could be declared in a generic body. Such an extension could have a task component, for example, and an object of that type could be passed to a dispatching operation of a nonlimited ancestor type. That operation could try to copy the object with the task component. That would be bad. So we disallow this as well.

If TT were declared as abstract, then we could have the same problem with abstract procedures.

We considered disallowing all tagged types in a generic body, for simplicity. We decided not to go that far, in order to avoid unnecessary restrictions.

We also considered trying make the accessibility level part of the contract; i.e. invent some way of saying (in the generic\_declaration) “all instances of this generic unit will have the same accessibility level as the generic\_declaration.” Unfortunately, that doesn't solve the part of the problem having to do with abstract types.

*This paragraph was deleted.*

**Ramification:** {AI95-00344} This rule applies to types with ancestors (directly or indirectly) of formal interface types (see 12.5.5), formal tagged private types (see 12.5.1), and formal derived private types whose ancestor type is tagged (see 12.5.1).

#### Static Semantics

{AI95-00391-01} A record extension is a *null extension* if its declaration has no known\_discriminant\_part and its record\_extension\_part includes no component\_declarations.

#### Dynamic Semantics

The elaboration of a record\_extension\_part consists of the elaboration of the record\_definition.

#### NOTES

71 The term “type extension” refers to a type as a whole. The term “extension part” refers to the piece of text that defines the additional components (if any) the type extension has relative to its specified ancestor type.

**Discussion:** We considered other terminology, such as “extended type.” However, the terms “private extended type” and “record extended type” did not convey the proper meaning. Hence, we have chosen to uniformly use the term “extension” as the type resulting from extending a type, with “private extension” being one produced by privately extending the type, and “record extension” being one produced by extending the type with an additional record-like set of components. Note also that the term “type extension” refers to the result of extending a type in the language Oberon as well (though there the term “extended type” is also used, interchangeably, perhaps because Oberon doesn't have the concept of a “private extension”).

72 {AI95-00344-01} When an extension is declared immediately within a body, primitive subprograms are inherited and are overridable, but new primitive subprograms cannot be added.

73 A name that denotes a component (including a discriminant) of the parent type is not allowed within the record\_extension\_part. Similarly, a name that denotes a component defined within the record\_extension\_part is not allowed within the record\_extension\_part. It is permissible to use a name that denotes a discriminant of the record extension, providing there is a new known\_discriminant\_part in the enclosing type declaration. (The full rule is given in 3.8.)

8.a **Reason:** The restriction against depending on discriminants of the parent is to simplify the definition of extension aggregates. The restriction against using parent components in other ways is methodological; it presumably simplifies implementation as well.

9 74 Each visible component of a record extension has to have a unique name, whether the component is (visibly) inherited from the parent type or declared in the `record_extension_part` (see 8.3).

*Examples*

10 *Examples of record extensions (of types defined above in 3.9):*

```

11 type Painted_Point is new Point with
 record
 Paint : Color := White;
 end record;
 -- Components X and Y are inherited

12 Origin : constant Painted_Point := (X | Y => 0.0, Paint => Black);

13 type Literal is new Expression with
 record
 Value : Real;
 end record;
 -- a leaf in an Expression tree

14 type Expr_Ptr is access all Expression'Class;
 -- see 3.10

15 type Binary_Operation is new Expression with
 record
 Left, Right : Expr_Ptr;
 end record;
 -- an internal node in an Expression tree

16 type Addition is new Binary_Operation with null record;
 type Subtraction is new Binary_Operation with null record;
 -- No additional components needed for these extensions

17 Tree : Expr_Ptr :=
 new Addition'(
 Left => new Literal'(Value => 5.0),
 Right => new Subtraction'(
 Left => new Literal'(Value => 13.0),
 Right => new Literal'(Value => 7.0));

```

*Extensions to Ada 83*

17.a Type extension is a new concept.

*Extensions to Ada 95*

17.b/2 {AI95-00344-01} Type extensions now can be declared in more nested scopes than their parent types. Additional accessibility checks on allocators and return statements prevent objects from outliving their type.

*Wording Changes from Ada 95*

17.c/2 {AI95-00345-01} Added wording to prevent extending synchronized tagged types.

17.d/2 {AI95-00391-01} Defined null extension for use elsewhere.

## 3.9.2 Dispatching Operations of Tagged Types

1/2 {AI95-00260-02} {AI95-00335-01} The primitive subprograms of a tagged type, the subprograms declared by `formal_abstract_subprogram_declarations`, and the stream attributes of a specific tagged type that are available (see 13.13.2) at the end of the declaration list where the type is declared are called *dispatching operations*. [A dispatching operation can be called using a statically determined *controlling tag*, in which case the body to be executed is determined at compile time. Alternatively, the controlling tag can be dynamically determined, in which case the call *dispatches* to a body that is determined at run time;] such a call is termed a *dispatching call*. [As explained below, the properties of the operands and the context of a particular call on a dispatching operation determine how the controlling tag is determined,

and hence whether or not the call is a dispatching call. Run-time polymorphism is achieved when a dispatching operation is called by a dispatching call.]

**Reason:** {AI95-00335-01} For the stream attributes of a type declared immediately within a `package_specification` that has a partial view, the declaration list to consider is the visible part of the package. Stream attributes that are not available in the same declaration list are not dispatching as there is no guarantee that descendants of the type have available attributes (there is such a guarantee for visibly available attributes). If we allowed dispatching for any available attribute, then for attributes defined in the private part we could end up executing a nonexistent body. 1.a.1/2

*Language Design Principles*

The controlling tag determination rules are analogous to the overload resolution rules, except they deal with run-time type identification (tags) rather than compile-time type resolution. As with overload resolution, controlling tag determination may depend on operands or result context. 1.a

*Static Semantics*

{AI95-00260-02} {AI95-00416-01} {AI05-0076-1} A *call on a dispatching operation* is a call whose name or prefix denotes the declaration of a dispatching operation. A *controlling operand* in a call on a dispatching operation of a tagged type *T* is one whose corresponding formal parameter is of type *T* or is of an anonymous access type with designated type *T*; the corresponding formal parameter is called a *controlling formal parameter*. If the controlling formal parameter is an access parameter, the controlling operand is the object designated by the actual parameter, rather than the actual parameter itself. If the call is to a (primitive) function with result type *T* (a *function with a controlling result*), then the call has a *controlling result* — the context of the call can control the dispatching. Similarly, if the call is to a function with an access result type designating *T* (a *function with a controlling access result*), then the call has a *controlling access result*, and the context can similarly control dispatching. 2/3

**Ramification:** This definition implies that a call through the dereference of an access-to-subprogram value is never considered a call on a dispatching operation. Note also that if the prefix denotes a `renaming_declaration`, the place where the renaming occurs determines whether it is primitive; the thing being renamed is irrelevant. 2.a

A name or expression of a tagged type is either *statically* tagged, *dynamically* tagged, or *tag indeterminate*, according to whether, when used as a controlling operand, the tag that controls dispatching is determined statically by the operand's (specific) type, dynamically by its tag at run time, or from context. A `qualified_expression` or parenthesized expression is statically, dynamically, or indeterminately tagged according to its operand. For other kinds of names and expressions, this is determined as follows: 3

- {AI95-00416-01} The name or expression is *statically tagged* if it is of a specific tagged type and, if it is a call with a controlling result or controlling access result, it has at least one statically tagged controlling operand; 4/2

**Discussion:** It is illegal to have both statically tagged and dynamically tagged controlling operands in the same call -- see below. 4.a

- {AI95-00416-01} The name or expression is *dynamically tagged* if it is of a class-wide type, or it is a call with a controlling result or controlling access result and at least one dynamically tagged controlling operand; 5/2
- {AI95-00416-01} The name or expression is *tag indeterminate* if it is a call with a controlling result or controlling access result, all of whose controlling operands (if any) are tag indeterminate. 6/2

{8652/0010} {AI95-00127-01} [A `type_conversion` is statically or dynamically tagged according to whether the type determined by the `subtype_mark` is specific or class-wide, respectively.] For an object that is designated by an expression whose expected type is an anonymous access-to-specific tagged type, the object is dynamically tagged if the expression, ignoring enclosing parentheses, is of the form `X'Access`, where `X` is of a class-wide type, or is of the form `new T'(...)`, where `T` denotes a class-wide subtype. Otherwise, the object is statically or dynamically tagged according to whether the designated type of the type of the expression is specific or class-wide, respectively. 7/1

- 7.a **Ramification:** A `type_conversion` is never tag indeterminate, even if its operand is. A designated object is never tag indeterminate.
- 7.a.1/1 {8652/0010} {AI95-00127-01} Allocators and access attributes of class-wide types can be used as the controlling parameters of dispatching calls.

*Legality Rules*

- 8 A call on a dispatching operation shall not have both dynamically tagged and statically tagged controlling operands.
- 8.a **Reason:** This restriction is intended to minimize confusion between whether the dynamically tagged operands are implicitly converted to, or tag checked against the specific type of the statically tagged operand(s).
- 9/1 {8652/0010} {AI95-00127-01} If the expected type for an expression or `name` is some specific tagged type, then the expression or `name` shall not be dynamically tagged unless it is a controlling operand in a call on a dispatching operation. Similarly, if the expected type for an expression is an anonymous access-to-specific tagged type, then the object designated by the expression shall not be dynamically tagged unless it is a controlling operand in a call on a dispatching operation.
- 9.a **Reason:** This prevents implicit "truncation" of a dynamically-tagged value to the specific type of the target object/formal. An explicit conversion is required to request this truncation.
- 9.b/2 **Ramification:** {AI95-00252-01} This rule applies to all expressions or `names` with a specific expected type, not just those that are actual parameters to a dispatching call. This rule does not apply to a membership test whose `expression` is class-wide, since any type that covers the tested type is explicitly allowed. See 4.5.2. This rule also doesn't apply to a `selected_component` whose `selector_name` is a subprogram, since the rules explicitly say that the prefix may be class-wide (see 4.1.3).
- 10/2 {8652/0011} {AI95-00117-01} {AI95-00430-01} In the declaration of a dispatching operation of a tagged type, everywhere a subtype of the tagged type appears as a subtype of the profile (see 6.1), it shall statically match the first subtype of the tagged type. If the dispatching operation overrides an inherited subprogram, it shall be subtype conformant with the inherited subprogram. The convention of an inherited dispatching operation is the convention of the corresponding primitive operation of the parent or progenitor type. The default convention of a dispatching operation that overrides an inherited primitive operation is the convention of the inherited operation; if the operation overrides multiple inherited operations, then they shall all have the same convention. An explicitly declared dispatching operation shall not be of convention `Intrinsic`.
- 10.a **Reason:** These rules ensure that constraint checks can be performed by the caller in a dispatching call, and parameter passing conventions match up properly. A special rule on aggregates prevents values of a tagged type from being created that are outside of its first subtype.
- 11/2 {AI95-00416-01} The `default_expression` for a controlling formal parameter of a dispatching operation shall be tag indeterminate.
- 11.a/2 **Reason:** {AI95-00416-01} This rule ensures that the `default_expression` always produces the "correct" tag when called with or without dispatching, or when inherited by a descendant. If it were statically tagged, the default would be useless for a dispatching call; if it were dynamically tagged, the default would be useless for a nondispatching call.
- 11.1/2 {AI95-00404-01} If a dispatching operation is defined by a `subprogram_renaming_declaration` or the instantiation of a generic subprogram, any access parameter of the renamed subprogram or the generic subprogram that corresponds to a controlling access parameter of the dispatching operation, shall have a subtype that excludes `null`.
- 12 A given subprogram shall not be a dispatching operation of two or more distinct tagged types.
- 12.a **Reason:** This restriction minimizes confusion since multiple dispatching is not provided. The normal solution is to replace all but one of the tagged types with their class-wide types.
- 12.a.1/1 **Ramification:** {8652/0098} {AI95-00183-01} This restriction applies even if the partial view (see 7.3) of one or both of the types is untagged. This follows from the definition of dispatching operation: the operation is a dispatching operation anywhere the full views of the (tagged) types are visible.

- The explicit declaration of a primitive subprogram of a tagged type shall occur before the type is frozen (see 13.14). [For example, new dispatching operations cannot be added after objects or values of the type exist, nor after deriving a record extension from it, nor after a body.] 13
- Reason:** {AI95-00344-01} This rule is needed because (1) we don't want people dispatching to things that haven't been declared yet, and (2) we want to allow the static part of tagged type descriptors to be static (allocated statically, and initialized to link-time-known symbols). Suppose T2 inherits primitive P from T1, and then overrides P. Suppose P is called *before* the declaration of the overriding P. What should it dispatch to? If the answer is the new P, we've violated the first principle above. If the answer is the old P, we've violated the second principle. (A call to the new one necessarily raises Program\_Error, but that's beside the point.) 13.a/2
- Note that a call upon a dispatching operation of type *T* will freeze *T*. 13.b
- We considered applying this rule to all derived types, for uniformity. However, that would be upward incompatible, so we rejected the idea. As in Ada 83, for an untagged type, the above call upon P will call the old P (which is arguably confusing). 13.c
- Implementation Note:** {AI95-00326-01} Because of this rule, the type descriptor can be created (presumably containing linker symbols pointing at the not-yet-compiled bodies) at the first freezing point of the type. It also prevents, for a (nonincomplete) tagged type declared in a `package_specification`, overriding in the body or by a child subprogram. 13.d/2
- Ramification:** {AI95-00251-01} A consequence is that for a tagged type declaration in a `declarative_part`, only the last (overriding) primitive subprogram can be declared by a `subprogram_body`. (Other overrides must be provided by `subprogram_declarations`.) 13.e/2
- To be honest:** {AI05-0222-1} This rule applies only to "original" declarations and not to the completion of a primitive subprogram, even though a completion is technically an explicit declaration, and it may declare a primitive subprogram. 13.f/3

#### Dynamic Semantics

- For the execution of a call on a dispatching operation of a type *T*, the *controlling tag value* determines which subprogram body is executed. The controlling tag value is defined as follows: 14
- If one or more controlling operands are statically tagged, then the controlling tag value is *statically determined* to be the tag of *T*. 15
  - If one or more controlling operands are dynamically tagged, then the controlling tag value is not statically determined, but is rather determined by the tags of the controlling operands. If there is more than one dynamically tagged controlling operand, a check is made that they all have the same tag. If this check fails, Constraint\_Error is raised unless the call is a `function_call` whose `name` denotes the declaration of an equality operator (predefined or user defined) that returns Boolean, in which case the result of the call is defined to indicate inequality, and no `subprogram_body` is executed. This check is performed prior to evaluating any tag-indeterminate controlling operands. 16
- Reason:** Tag mismatch is considered an error (except for "=" and "/=") since the corresponding primitive subprograms in each specific type expect all controlling operands to be of the same type. For tag mismatch with an equality operator, rather than raising an exception, "=" returns False and "/=" returns True. No equality operator is actually invoked, since there is no common tag value to control the dispatch. Equality is a special case to be consistent with the existing Ada 83 principle that equality comparisons, even between objects with different constraints, never raise Constraint\_Error. 16.a
- {AI95-00196-01} If all of the controlling operands (if any) are tag-indeterminate, then: 17/2
    - {AI95-00239-01} {AI95-00416-01} If the call has a controlling result or controlling access result and is itself, or designates, a (possibly parenthesized or qualified) controlling operand of an enclosing call on a dispatching operation of a descendant of type *T*, then its controlling tag value is determined by the controlling tag value of this enclosing call; 18/2
- Discussion:** {AI95-00239-01} For code that a user can write explicitly, the only contexts that can control dispatching of a function with a controlling result of type *T* are those that involve controlling operands of the same type *T*: if the two types differ there is an illegality and the dynamic semantics are irrelevant. 18.a/2
- In the case of an inherited subprogram however, if a default expression is a function call, it may be of type *T* while the parameter is of a type derived from *T*. To cover this case, we talk about "a descendant of *T*" above. This is safe, 18.b/2

because if the type of the parameter is descended from the type of the function result, it is guaranteed to inherit or override the function, and this ensures that there will be an appropriate body to dispatch to. Note that abstract functions are not an issue here because the call to the function is a dispatching call, so it is guaranteed to always land on a concrete body.

- 18.1/2
- *{AI95-00196-01}* *{AI95-00416-01}* If the call has a controlling result or controlling access result and (possibly parenthesized, qualified, or dereferenced) is the expression of an `assignment_statement` whose target is of a class-wide type, then its controlling tag value is determined by the target;
- 19
- Otherwise, the controlling tag value is statically determined to be the tag of type *T*.
- 19.a
- Ramification:** This includes the cases of a tag-indeterminate procedure call, and a tag-indeterminate `function_call` that is used to initialize a class-wide formal parameter or class-wide object.
- 20/3
- {AI95-00345-01}* *{AI05-0126-1}* For the execution of a call on a dispatching operation, the action performed is determined by the properties of the corresponding dispatching operation of the specific type identified by the controlling tag value:
- 20.1/3
- *{AI05-0126-1}* if the corresponding operation is explicitly declared for this type, [even if the declaration occurs in a private part], then the action comprises an invocation of the explicit body for the operation;
- 20.2/3
- *{AI95-00345-01}* *{AI05-0126-1}* if the corresponding operation is implicitly declared for this type and is implemented by an entry or protected subprogram (see 9.1 and 9.4), then the action comprises a call on this entry or protected subprogram, with the target object being given by the first actual parameter of the call, and the actual parameters of the entry or protected subprogram being given by the remaining actual parameters of the call, if any;
- 20.3/3
- *{AI05-0197-1}* if the corresponding operation is a predefined operator then the action comprises an invocation of that operator;
- 20.4/3
- *{AI95-00345-01}* *{AI05-0126-1}* *{AI05-0197-1}* *{AI05-0250-1}* *{AI05-0254-1}* otherwise, the action is the same as the action for the corresponding operation of the parent type or progenitor type from which the operation was inherited except that additional invariant checks (see 7.3.2) and class-wide postcondition checks (see 6.1.1) may apply. If there is more than one such corresponding operation, the action is that for the operation that is not a null procedure, if any; otherwise, the action is that of an arbitrary one of the operations.
- 20.a/3
- This paragraph was deleted. {AI05-0126-1}*
- 20.a.1/3
- Ramification:** *{AI05-0005-1}* *{AI05-0126-1}* “Corresponding dispatching operation” refers to the inheritance relationship between subprograms. Primitive operations are always inherited for a type *T*, but they might not be declared if the primitive operation is never visible within the immediate scope of the type *T*. If no corresponding operation is declared, the last bullet is used and the corresponding operation of the parent type is executed (an explicit body that happens to have the same name and profile is not called in that case).
- 20.a.2/3
- {AI05-0005-1}* *{AI05-0126-1}* We have to talk about progenitors in the last bullet in case the corresponding operation is a null procedure inherited from an interface. In that case, the parent type might not even have the operation in question.
- 20.a.3/3
- {AI05-0197-1}* For the last bullet, if there are multiple corresponding operations for the parent and progenitors, all but one of them have to be a null procedure. (If the progenitors declared abstract routines, there would have to be an explicit overriding of the operation, and then the first bullet would apply.) We call the nonnull routine if one exists.
- 20.a.4/3
- {AI05-0126-1}* Any explicit declaration for an inherited corresponding operation has to be an overriding routine. These rules mean that a dispatching call executes the overriding routine (if any) for the specific type.
- 20.b/3
- Reason:** *{AI05-0005-1}* The wording of the above rules is intended to ensure that the same body is executed for a given tag, whether that tag is determined statically or dynamically. For a type declared in a package, it doesn't matter whether a given subprogram is overridden in the visible part or the private part, and it doesn't matter whether the call is inside or outside the package. For example:
- 20.c
- ```
package P1 is
  type T1 is tagged null record;
  procedure Op_A(Arg : in T1);
  procedure Op_B(Arg : in T1);
end P1;
```

```

with P1; use P1;
package P2 is
  type T2 is new T1 with null record;
  procedure Op_A(Param : in T2);
private
  procedure Op_B(Param : in T2);
end P2;

with P1; with P2;
procedure Main is
  X : P2.T2;
  Y : P1.T1'Class := X;
begin
  P2.Op_A(Param => X); -- Nondispatching call to a dispatching operation.
  P1.Op_A(Arg => Y); -- Dispatching call.
  P2.Op_B(Arg => X); -- Nondispatching call to a dispatching operation.
  P1.Op_B(Arg => Y); -- Dispatching call.
end Main;

```

The two calls to `Op_A` both execute the body of `Op_A` that has to occur in the body of package `P2`. Similarly, the two calls to `Op_B` both execute the body of `Op_B` that has to occur in the body of package `P2`, even though `Op_B` is overridden in the private part of `P2`. Note, however, that the formal parameter names are different for `P2.Op_A` versus `P2.Op_B`. The overriding declaration for `P2.Op_B` is not visible in `Main`, so the name in the call actually denotes the implicit declaration of `Op_B` inherited from `T1`.

If a call occurs in the program text before an overriding, which can happen only if the call is part of a default expression, the overriding will still take effect for that call.

Implementation Note: Even when a tag is not *statically determined*, a compiler might still be able to figure it out and thereby avoid the overhead of run-time dispatching.

NOTES

- 75 The body to be executed for a call on a dispatching operation is determined by the tag; it does not matter whether that tag is determined statically or dynamically, and it does not matter whether the subprogram's declaration is visible at the place of the call. 21
- 76 {AI95-00260-02} This subclause covers calls on dispatching subprograms of a tagged type. Rules for tagged type membership tests are described in 4.5.2. Controlling tag determination for an `assignment_statement` is described in 5.2. 22/2
- 77 A dispatching call can dispatch to a body whose declaration is not visible at the place of the call. 23
- 78 A call through an access-to-subprogram value is never a dispatching call, even if the access value designates a dispatching operation. Similarly a call whose prefix denotes a `subprogram_renaming_declaration` cannot be a dispatching call unless the renaming itself is the declaration of a primitive subprogram. 24

Extensions to Ada 83

The concept of dispatching operations is new. 24.a

Incompatibilities With Ada 95

{AI95-00404-01} If a dispatching operation is defined by a `subprogram_renaming_declaration`, and it has a controlling access parameter, Ada 2005 requires the subtype of the parameter to exclude null. The same applies to instantiations. This is required so that all calls to the subprogram operate the same way (controlling access parameters have to exclude null so that dispatching calls will work). Since Ada 95 didn't have the notion of access subtypes that exclude null, and all access parameters excluded null, it had no such rules. These rules will require the addition of an explicit **not null** on nondispatching operations that are later renamed to be dispatching, or on a generic that is used to define a dispatching operation. 24.b/2

Extensions to Ada 95

{AI95-00416-01} Functions that have an access result type can be dispatching in the same way as a function that returns a tagged object directly. 24.c/2

Wording Changes from Ada 95

{8652/0010} {AI95-00127-01} {AI05-0299-1} **Corrigendum:** Allocators and access attributes of objects of class-wide types can be used as the controlling parameter in a dispatching calls. This was an oversight in the definition of Ada 95. (See 3.10.2 and 4.8). 24.d/3

{8652/0011} {AI95-00117-01} {AI95-00430-01} **Corrigendum:** Corrected the conventions of dispatching operations. This is extended in Ada 2005 to cover operations inherited from progenitors, and to ensure that the conventions of all inherited operations are the same. 24.e/2

- 24.f/2 {AI95-00196-01} Clarified the wording to ensure that functions with no controlling operands are tag-indeterminate, and to describe that the controlling tag can come from the target of an `assignment_statement`.
- 24.g/2 {AI95-00239-01} Fixed the wording to cover default expressions inherited by derived subprograms. A literal reading of the old wording would have implied that operations would be called with objects of the wrong type.
- 24.h/2 {AI95-00260-02} An abstract formal subprogram is a dispatching operation, even though it is not a primitive operation. See 12.6, “Formal Subprograms”.
- 24.i/2 {AI95-00345-01} Dispatching calls include operations implemented by entries and protected operations, so we have to update the wording to reflect that.
- 24.j/2 {AI95-00335-01} A stream attribute of a tagged type is usually a dispatching operation, even though it is not a primitive operation. If they weren't dispatching, T'Class'Input and T'Class'Output wouldn't work.

Wording Changes from Ada 2005

- 24.k/3 {AI05-0076-1} **Correction:** Defined “function with a controlling result”, as it is used in 3.9.3.
- 24.l/3 {AI05-0126-1} {AI05-0197-1} **Correction:** Corrected holes in the definition of dynamic dispatching: the behavior for operations that are never declared and/or inherited from a progenitor were not specified.

3.9.3 Abstract Types and Subprograms

- 1/2 {AI95-00345-01} [An *abstract type* is a tagged type intended for use as an ancestor of other types, but which is not allowed to have objects of its own. An *abstract subprogram* is a subprogram that has no body, but is intended to be overridden at some point when inherited. Because objects of an abstract type cannot be created, a dispatching call to an abstract subprogram always dispatches to some overriding body.]
- 1.a.1/2 **Glossary entry:** An abstract type is a tagged type intended for use as an ancestor of other types, but which is not allowed to have objects of its own.

Language Design Principles

- 1.a/3 {AI05-0299-1} An abstract subprogram has no body, so the rules in this subclause are designed to ensure (at compile time) that the body will never be invoked. We do so primarily by disallowing the creation of values of the abstract type. Therefore, since type conversion and parameter passing don't change the tag, we know we will never get a class-wide value with a tag identifying an abstract type. This means that we only have to disallow nondispatching calls on abstract subprograms (dispatching calls will never reach them).

Syntax

- 1.1/3 {AI95-00218-03} {AI95-00348-01} {AI05-0183-1} **abstract_subprogram_declaration ::=**
[overriding_indicator]
subprogram_specification is abstract
[aspect_specification];

Static Semantics

- 1.2/2 {AI95-00345-01} Interface types (see 3.9.4) are abstract types. In addition, a tagged type that has the reserved word **abstract** in its declaration is an abstract type. The class-wide type (see 3.4.1) rooted at an abstract type is not itself an abstract type.

Legality Rules

- 2/2 {AI95-00345-01} Only a tagged type shall have the reserved word **abstract** in its declaration.
- 2.a **Ramification:** Untagged types are never abstract, even though they can have primitive abstract subprograms. Such subprograms cannot be called, unless they also happen to be dispatching operations of some tagged type, and then only via a dispatching call.
- 2.b Class-wide types are never abstract. If T is abstract, then it is illegal to declare a stand-alone object of type T, but it is OK to declare a stand-alone object of type T'Class; the latter will get a tag from its initial value, and this tag will necessarily be different from T'Tag.

{AI95-00260-02} {AI95-00348-01} A subprogram declared by an `abstract_subprogram_declaration` or a `formal_abstract_subprogram_declaration` (see 12.6) is an *abstract subprogram*. If it is a primitive subprogram of a tagged type, then the tagged type shall be abstract. 3/2

Ramification: Note that for a private type, this applies to both views. The following is illegal: 3.a

```
package P is
  type T is abstract tagged private;
  function Foo (X : T) return Boolean is abstract; -- Illegal!
private
  type T is tagged null record; -- Illegal!
  X : T;
  Y : Boolean := Foo (T'Class (X));
end P; 3.b
```

The full view of T is not abstract, but has an abstract operation Foo, which is illegal. The two lines marked "*-- Illegal!*" are illegal when taken together. 3.c

Reason: {AI95-00310-01} We considered disallowing untagged types from having abstract primitive subprograms. However, we rejected that plan, because it introduced some silly anomalies, and because such subprograms are harmless. For example: 3.d/2

```
package P is
  type Field_Size is range 0..100;
  type T is abstract tagged null record;
  procedure Print(X : in T; F : in Field_Size := 0) is abstract;
  . . .
package Q is
  type My_Field_Size is new Field_Size;
  -- implicit declaration of Print(X : T; F : My_Field_Size := 0) is abstract;
end Q; 3.e/1
```

It seemed silly to make the derivative of My_Field_Size illegal, just because there was an implicitly declared abstract subprogram that was not primitive on some tagged type. Other rules could be formulated to solve this problem, but the current ones seem like the simplest. 3.f

{AI95-00310-01} In Ada 2005, abstract primitive subprograms of an untagged type may be used to “undefine” an operation. 3.g/2

Ramification: {AI95-00260-02} Note that the second sentence does not apply to abstract formal subprograms, as they are never primitive operations of a type. 3.h/2

{AI95-00251-01} {AI95-00334-01} {AI95-00391-01} {AI05-0097-1} {AI05-0198-1} If a type has an implicitly declared primitive subprogram that is inherited or is a predefined operator, and the corresponding primitive subprogram of the parent or ancestor type is abstract or is a function with a controlling access result, or if a type other than a nonabstract null extension inherits a function with a controlling result, then: 4/3

Ramification: {AI05-0068-1} These rules apply to each view of the type individually. That is necessary to preserve privacy. For instance, in the following example: 4.a/3

```
package P is
  type I is interface;
  procedure Op (X : I) is abstract;
end P; 4.b/3

with P;
package Q is
  type T is abstract new P.I with private;
  -- Op inherited here.
private
  type T is abstract new P.I with null record;
  procedure Op (X : T) is null;
end Q; 4.c/3

with Q;
package R is
  type T2 is new Q.T with null record;
  -- Illegal. Op inherited here, but requires overriding.
end R; 4.d/3
```

If this did not depend on the view, this would be legal. But in that case, the fact that Op is overridden in the private part would be visible; package R would have to be illegal if no overriding was in the private part. 4.e/3

Note that this means that whether an inherited subprogram is abstract or concrete depends on where it inherited. In the case of Q, Q.Op in the visible part is abstract, while Q.Op in the private part is concrete. That is, R is illegal since it is 4.f/3

an unrelated unit (and thus it cannot see the private part), but if R had been a private child of Q, it would have been legal.

- 5/2 • *{AI95-00251-01}* *{AI95-00334-01}* If the type is abstract or untagged, the implicitly declared subprogram is *abstract*.
- 5.a **Ramification:** Note that it is possible to override a concrete subprogram with an abstract one.
- 6/2 • *{AI95-00391-01}* Otherwise, the subprogram shall be overridden with a nonabstract subprogram or, in the case of a private extension inheriting a function with a controlling result, have a full type that is a null extension[; for a type declared in the visible part of a package, the overriding may be either in the visible or the private part]. Such a subprogram is said to *require overriding*. However, if the type is a generic formal type, the subprogram need not be overridden for the formal type itself; [a nonabstract version will necessarily be provided by the actual type.]
- 6.a/2 **Reason:** *{AI95-00228-01}* *{AI95-00391-01}* A function that returns the parent type requires overriding for a type extension (or becomes abstract for an abstract type) because conversion from a parent type to a type extension is not defined, and function return semantics is defined in terms of conversion (other than for a null extension; see below). (Note that parameters of mode **in out** or **out** do not have this problem, because the tag of the actual is not changed.)
- 6.b Note that the overriding required above can be in the private part, which allows the following:
- 6.c
- ```
package Pack1 is
 type Ancestor is abstract ...;
 procedure Do_Something(X : in Ancestor) is abstract;
end Pack1;
```
- 6.d
- ```
with Pack1; use Pack1;
package Pack2 is
  type T1 is new Ancestor with record ...;
  -- A concrete type.
  procedure Do_Something(X : in T1); -- Have to override.
end Pack2;
```
- 6.e
- ```
with Pack1; use Pack1;
with Pack2; use Pack2;
package Pack3 is
 type T2 is new Ancestor with private;
 -- A concrete type.
private
 type T2 is new T1 with -- Parent different from ancestor.
 record ... end record;
 -- Here, we inherit Pack2.Do_Something.
end Pack3;
```
- 6.f/2 *{AI95-00228-01}* T2 inherits an abstract Do\_Something, but T2 is not abstract, so Do\_Something has to be overridden. However, it is OK to override it in the private part. In this case, we override it by inheriting a concrete version from a different type. Nondispatching calls to Pack3.Do\_Something are allowed both inside and outside package Pack3, as the client “knows” that the subprogram was necessarily overridden somewhere.
- 6.g/2 *{AI95-00391-01}* For a null extension, the result of a function with a controlling result is defined in terms of an extension\_aggregate with a **null record** extension part (see 3.4). This means that these restrictions on functions with a controlling result do not have to apply to null extensions.
- 6.h/2 *{AI95-00391-01}* However, functions with controlling access results still require overriding. Changing the tag in place might clobber a preexisting object, and allocating new memory would possibly change the pool of the object, leading to storage leaks. Moreover, copying the object isn't possible for limited types. We don't need to restrict functions that have an access return type of an untagged type, as derived types with primitive subprograms have to have the same representation as their parent type.
- 7 A call on an abstract subprogram shall be a dispatching call; [nondispatching calls to an abstract subprogram are not allowed.]
- 7.a/2 **Ramification:** *{AI95-00310-01}* If an abstract subprogram is not a dispatching operation of some tagged type, then it cannot be called at all. In Ada 2005, such subprograms are not even considered by name resolution (see 6.4).
- 8/3 *{AI05-0073-1}* *{AI05-0203-1}* The type of an aggregate, or of an object created by an object\_declaration or an allocator, or a generic formal object of mode **in**, shall not be abstract. The type of the target of an assignment operation (see 5.2) shall not be abstract. The type of a component shall not be abstract. If the result type of a function is abstract, then the function shall be abstract. If a function has

an access result type designating an abstract type, then the function shall be abstract. The type denoted by a `return_subtype_indication` (see 6.5) shall not be abstract. A generic function shall not have an abstract result type or an access result type designating an abstract type.

**Reason:** This ensures that values of an abstract type cannot be created, which ensures that a dispatching call to an abstract subprogram will not try to execute the nonexistent body. 8.a

Generic formal objects of mode **in** are like constants; therefore they should be forbidden for abstract types. Generic formal objects of mode **in out** are like renamings; therefore, abstract types are OK for them, though probably not terribly useful. 8.b

{AI05-0073-1} Generic functions returning a formal abstract type are illegal because any instance would have to be instantiated with a nonabstract type in order to avoid violating the function rule (generic functions cannot be declared abstract). But that would be an implied contract; it would be better for the contract to be explicit by the formal type not being declared abstract. Moreover, the implied contract does not add any capability. 8.c/3

If a partial view is not abstract, the corresponding full view shall not be abstract. If a generic formal type is abstract, then for each primitive subprogram of the formal that is not abstract, the corresponding primitive subprogram of the actual shall not be abstract. 9

**Discussion:** By contrast, we allow the actual type to be nonabstract even if the formal type is declared abstract. Hence, the most general formal tagged type possible is "**type T(<>) is abstract tagged limited private;**". 9.a

For an abstract private extension declared in the visible part of a package, it is only possible for the full type to be nonabstract if the private extension has no abstract dispatching operations. 9.b

**To be honest:** {AI95-00294-01} In the sentence about primitive subprograms above, there is some ambiguity as to what is meant by “corresponding” in the case where an inherited operation is overridden. This is best explained by an example, where the implicit declarations are shown as comments: 9.c/2

```

package P1 is
 type T1 is abstract tagged null record;
 procedure P (X : T1); -- (1)
end P1;
package P2 is
 type T2 is abstract new P1.T1 with null record;
 -- procedure P (X : T2); -- (2)
 procedure P (X : T2) is abstract; -- (3)
end P2;
generic
 type D is abstract new P1.T1 with private;
 -- procedure P (X : D); -- (4)
procedure G (X : D);
procedure I is new G (P2.T2); -- Illegal.

```

9.d/2

9.e/2

9.f/2

9.g/2

Type T2 inherits a nonabstract procedure P (2) from the primitive procedure P (1) of T1. P (2) is overridden by the explicitly declared abstract procedure P (3). Type D inherits a nonabstract procedure P (4) from P (1). In instantiation I, the operation corresponding to P (4) is the one which is not overridden, that is, P (3): the overridden operation P (2) does not “reemerge”. Therefore, the instantiation is illegal. 9.h/2

{AI05-0073-1} For an abstract type declared in a visible part, an abstract primitive subprogram shall not be declared in the private part, unless it is overriding an abstract subprogram implicitly declared in the visible part. For a tagged type declared in a visible part, a primitive function with a controlling result or a controlling access result shall not be declared in the private part, unless it is overriding a function implicitly declared in the visible part. 10/3

**Reason:** The “visible part” could be that of a package or a generic package. This rule is needed because a nonabstract type extension declared outside the package would not know about any abstract primitive subprograms or primitive functions with controlling results declared in the private part, and wouldn't know that they need to be overridden with nonabstract subprograms. The rule applies to a tagged record type or record extension declared in a visible part, just as to a tagged private type or private extension. The rule applies to explicitly and implicitly declared abstract subprograms: 10.a

```

package Pack is
 type T is abstract new T1 with private;
private
 type T is abstract new T2 with record ... end record;
 ...
end Pack;

```

10.b

- 10.c The above example would be illegal if T1 has a nonabstract primitive procedure P, but T2 overrides P with an abstract one; the private part should override P with a nonabstract version. On the other hand, if the P were abstract for both T1 and T2, the example would be legal as is.
- 11/2 {AI95-00260-02} A generic actual subprogram shall not be an abstract subprogram unless the generic formal subprogram is declared by a `formal_abstract_subprogram_declaration`. The prefix of an `attribute_reference` for the `Access`, `Unchecked_Access`, or `Address` attributes shall not denote an abstract subprogram.
- 11.a **Ramification:** An `abstract_subprogram_declaration` is not syntactically a `subprogram_declaration`. Nonetheless, an abstract subprogram is a subprogram, and an `abstract_subprogram_declaration` is a declaration of a subprogram.
- 11.b/2 {AI95-00260-02} The part about generic actual subprograms includes those given by default. Of course, an abstract formal subprogram's actual subprogram can be abstract.

*Dynamic Semantics*

- 11.1/2 {AI95-00348-01} The elaboration of an `abstract_subprogram_declaration` has no effect.
- NOTES
- 12 79 Abstractness is not inherited; to declare an abstract type, the reserved word **abstract** has to be used in the declaration of the type extension.
- 12.a **Ramification:** A derived type can be abstract even if its parent is not. Similarly, an inherited concrete subprogram can be overridden with an abstract subprogram.
- 13 80 A class-wide type is never abstract. Even if a class is rooted at an abstract type, the class-wide type for the class is not abstract, and an object of the class-wide type can be created; the tag of such an object will identify some nonabstract type in the class.

*Examples*

- 14 *Example of an abstract type representing a set of natural numbers:*

```

15 package Sets is
 subtype Element_Type is Natural;
 type Set is abstract tagged null record;
 function Empty return Set is abstract;
 function Union(Left, Right : Set) return Set is abstract;
 function Intersection(Left, Right : Set) return Set is abstract;
 function Unit_Set(Element : Element_Type) return Set is abstract;
 procedure Take(Element : out Element_Type;
 From : in out Set) is abstract;
end Sets;
```

## NOTES

- 16 81 *Notes on the example:* Given the above abstract type, one could then derive various (nonabstract) extensions of the type, representing alternative implementations of a set. One might use a bit vector, but impose an upper bound on the largest element representable, while another might use a hash table, trading off space for flexibility.
- 16.a **Discussion:** One way to export a type from a package with some components visible and some components private is as follows:
- ```

16.b package P is
    type Public_Part is abstract tagged
        record
            ...
        end record;
    type T is new Public_Part with private;
    ...
private
    type T is new Public_Part with
        record
            ...
        end record;
end P;
```
- 16.c The fact that `Public_Part` is abstract tells clients they have to create objects of type `T` instead of `Public_Part`. Note that the public part has to come first; it would be illegal to declare a private type `Private_Part`, and then a record extension `T` of it, unless `T` were in the private part after the full declaration of `Private_Part`, but then clients of the package would not have visibility to `T`.

Extensions to Ada 95

{AI95-00391-01} It is not necessary to override functions with a controlling result for a null extension. This makes it easier to derive a tagged type to complete a private type. 16.d/2

Wording Changes from Ada 95

{AI95-00251-01} {AI95-00345-01} Updated the wording to reflect the addition of interface types (see 3.9.4). 16.e/2

{AI95-00260-02} Updated the wording to reflect the addition of abstract formal subprograms (see 12.6). 16.f/2

{AI95-00334-01} The wording of shall-be-overridden was clarified so that it clearly applies to abstract predefined equality. 16.g/2

{AI95-00348-01} Moved the syntax and elaboration rule for `abstract_subprogram_declaration` here, so the syntax and most of the semantics are together (which is consistent with null procedures). 16.h/2

{AI95-00391-01} We define the term *require overriding* to make other wording easier to understand. 16.i/2

Incompatibilities With Ada 2005

{AI05-0073-1} **Correction:** Added rules to eliminate holes with controlling access results and generic functions that return abstract types. While these changes are technically incompatible, it is unlikely that they could be used in a program without violating some other rule of the use of abstract types. 16.j/3

{AI05-0097-1} **Correction:** Corrected a minor glitch having to do with abstract null extensions. The Ada 2005 rule allowed such extensions to inherit concrete operations in some rare cases. It is unlikely that these cases exist in user code. 16.k/3

Extensions to Ada 2005

{AI05-0183-1} An optional `aspect_specification` can be used in an `abstract_subprogram_declaration`. This is described in 13.1.1.1. 16.l/3

Wording Changes from Ada 2005

{AI05-0198-1} **Correction:** Clarified that the predefined operator corresponding to an inherited abstract operator is also abstract. The Ada 2005 rules caused the predefined operator and the inherited operator to override each other, which is weird. But the effect is the same either way (the operator is not considered for resolution). 16.m/3

{AI05-0203-1} **Correction:** Added wording to disallow abstract return objects. These were illegal in Ada 2005 by other rules; the extension to support class-wide type better opened a hole which has now been plugged. 16.n/3

3.9.4 Interface Types

{AI95-00251-01} {AI95-00345-01} [An interface type is an abstract tagged type that provides a restricted form of multiple inheritance. A tagged type, task type, or protected type may have one or more interface types as ancestors.] 1/2

Glossary entry: An interface type is a form of abstract tagged type which has no components or concrete operations except possibly null procedures. Interface types are used for composing other interfaces and tagged types and thereby provide multiple inheritance. Only an interface type can be used as a progenitor of another type. 1.a/2

Language Design Principles

{AI95-00251-01} {AI95-00345-01} The rules are designed so that an interface can be used as either a parent type or a progenitor type without changing the meaning. That's important so that the order that interfaces are specified in a `derived_type_definition` is not significant. In particular, we want: 1.b/2

```
type Con1 is new Int1 and Int2 with null record; 1.c/2
type Con2 is new Int2 and Int1 with null record;
```

to mean exactly the same thing. 1.d/2

Syntax

{AI95-00251-01} {AI95-00345-01} `interface_type_definition ::=`
`[limited | task | protected | synchronized] interface [and interface_list]` 2/2

3./2 `{AI95-00251-01} {AI95-00419-01} interface_list ::=`
`interface_subtype_mark {and interface_subtype_mark}`

Static Semantics

4./2 `{AI95-00251-01}` An interface type (also called an *interface*) is a specific abstract tagged type that is defined by an `interface_type_definition`.

5./2 `{AI95-00345-01}` An interface with the reserved word **limited**, **task**, **protected**, or **synchronized** in its definition is termed, respectively, a *limited interface*, a *task interface*, a *protected interface*, or a *synchronized interface*. In addition, all task and protected interfaces are synchronized interfaces, and all synchronized interfaces are limited interfaces.

5.a./2 **Glossary entry:** A synchronized entity is one that will work safely with multiple tasks at one time. A synchronized interface can be an ancestor of a task or a protected type. Such a task or protected type is called a synchronized tagged type.

6./2 `{AI95-00345-01} {AI95-00443-01}` [A task or protected type derived from an interface is a tagged type.] Such a tagged type is called a *synchronized* tagged type, as are synchronized interfaces and private extensions whose declaration includes the reserved word **synchronized**.

6.a./2 **Proof:** The full definition of tagged types given in 3.9 includes task and protected types derived from interfaces.

6.b./2 **Ramification:** The class-wide type associated with a tagged task type (including a task interface type) is a task type, because “task” is one of the language-defined classes of types (see 3.2). However, the class-wide type associated with an interface is *not* an interface type, as “interface” is *not* one of the language-defined classes (as it is not closed under derivation). In this sense, “interface” is similar to “abstract”. The class-wide type associated with an interface is a concrete (nonabstract) indefinite tagged composite type.

6.c./2 “Private extension” includes generic formal private extensions, as explained in 12.5.1.

7./2 `{AI95-00345-01}` A task interface is an [abstract] task type. A protected interface is an [abstract] protected type.

7.a./2 **Proof:** The “abstract” follows from the definition of an interface type.

7.b./2 **Reason:** This ensures that task operations (like abort and the Terminated attribute) can be applied to a task interface type and the associated class-wide type. While there are no protected type operations, we apply the same rule to protected interfaces for consistency.

8./2 `{AI95-00251-01}` [An interface type has no components.]

8.a./2 **Proof:** This follows from the syntax and the fact that discriminants are not allowed for interface types.

9./2 `{AI95-00419-01}` An `interface_subtype_mark` in an `interface_list` names a *progenitor subtype*; its type is the *progenitor type*. An interface type inherits user-defined primitive subprograms from each progenitor type in the same way that a derived type inherits user-defined primitive subprograms from its progenitor types (see 3.4).

9.a./2 **Glossary entry:** A progenitor of a derived type is one of the types given in the definition of the derived type other than the first. A progenitor is always an interface type. Interfaces, tasks, and protected types may also have progenitors.

Legality Rules

10./2 `{AI95-00251-01}` All user-defined primitive subprograms of an interface type shall be abstract subprograms or null procedures.

11./2 `{AI95-00251-01}` The type of a subtype named in an `interface_list` shall be an interface type.

12./2 `{AI95-00251-01} {AI95-00345-01}` A type derived from a nonlimited interface shall be nonlimited.

13./2 `{AI95-00345-01}` An interface derived from a task interface shall include the reserved word **task** in its definition; any other type derived from a task interface shall be a private extension or a task type declared by a task declaration (see 9.1).

{AI95-00345-01} An interface derived from a protected interface shall include the reserved word **protected** in its definition; any other type derived from a protected interface shall be a private extension or a protected type declared by a protected declaration (see 9.4). 14/2

{AI95-00345-01} An interface derived from a synchronized interface shall include one of the reserved words **task**, **protected**, or **synchronized** in its definition; any other type derived from a synchronized interface shall be a private extension, a task type declared by a task declaration, or a protected type declared by a protected declaration. 15/2

Reason: We require that an interface descendant of a task, protected, or synchronized interface repeat the explicit kind of interface it will be, rather than simply inheriting it, so that a reader is always aware of whether the interface provides synchronization and whether it may be implemented only by a task or protected type. The only place where inheritance of the kind of interface might be useful would be in a generic if you didn't know the kind of the actual interface. However, the value of that is low because you cannot implement an interface properly if you don't know whether it is a task, protected, or synchronized interface. Hence, we require the kind of the actual interface to match the kind of the formal interface (see 12.5.5). 15.a/2

{AI95-00345-01} No type shall be derived from both a task interface and a protected interface. 16/2

Reason: This prevents a single private extension from inheriting from both a task and a protected interface. For a private type, there can be no legal completion. For a generic formal derived type, there can be no possible matching type (so no instantiation could be legal). This rule provides early detection of the errors. 16.a

{AI95-00251-01} In addition to the places where Legality Rules normally apply (see 12.3), these rules apply also in the private part of an instance of a generic unit. 17/2

Ramification: {AI05-0299-1} This paragraph is intended to apply to all of the Legality Rules in this subclause. We cannot allow interface types which do not obey these rules, anywhere. Luckily, deriving from a formal type (which might be an interface) is not allowed for any tagged types in a generic body. So checking in the private part of a generic covers all of the cases. 17.a/3

Dynamic Semantics

{AI95-00251-01} {AI05-0070-1} The elaboration of an `interface_type_definition` creates the interface type and its first subtype. 18/3

Discussion: There is no other effect. An `interface_list` is made up of `subtype_marks`, which do not need to be elaborated, so the `interface_list` does not either. This is consistent with the handling of `discriminant_parts`. 18.a/3

NOTES

82 {AI95-00411-01} Nonlimited interface types have predefined nonabstract equality operators. These may be overridden with user-defined abstract equality operators. Such operators will then require an explicit overriding for any nonabstract descendant of the interface. 19/2

Examples

{AI95-00433-01} *Example of a limited interface and a synchronized interface extending it:* 20/2

```
type Queue is limited interface; 21/2
```

```
procedure Append(Q : in out Queue; Person : in Person_Name) is abstract;
```

```
procedure Remove_First(Q : in out Queue;
```

```
    Person : out Person_Name) is abstract;
```

```
function Cur_Count(Q : in Queue) return Natural is abstract;
```

```
function Max_Count(Q : in Queue) return Natural is abstract;
```

```
-- See 3.10.1 for Person_Name.
```

```
{AI05-0004-1} Queue_Error : exception; 22/3
```

```
-- Append raises Queue_Error if Cur_Count(Q) = Max_Count(Q)
```

```
-- Remove_First raises Queue_Error if Cur_Count(Q) = 0
```

```
type Synchronized_Queue is synchronized interface and Queue; -- see 9.11 23/2
```

```
procedure Append_Wait(Q : in out Synchronized_Queue;
```

```
    Person : in Person_Name) is abstract;
```

```
procedure Remove_First_Wait(Q : in out Synchronized_Queue;
```

```
    Person : out Person_Name) is abstract;
```

```
...
```

24/2

```

25/2  procedure Transfer(From   : in out Queue'Class;
                    To     : in out Queue'Class;
                    Number : in   Natural := 1) is
    Person : Person_Name;
begin
    for I in 1..Number loop
        Remove_First(From, Person);
        Append(To, Person);
    end loop;
end Transfer;

```

26/2 This defines a Queue interface defining a queue of people. (A similar design could be created to define any kind of queue simply by replacing Person_Name by an appropriate type.) The Queue interface has four dispatching operations, Append, Remove_First, Cur_Count, and Max_Count. The body of a class-wide operation, Transfer is also shown. Every nonabstract extension of Queue must provide implementations for at least its four dispatching operations, as they are abstract. Any object of a type derived from Queue may be passed to Transfer as either the From or the To operand. The two operands need not be of the same type in any given call.

27/2 The Synchronized_Queue interface inherits the four dispatching operations from Queue and adds two additional dispatching operations, which wait if necessary rather than raising the Queue_Error exception. This synchronized interface may only be implemented by a task or protected type, and as such ensures safe concurrent access.

28/2 *{AI95-00433-01} Example use of the interface:*

```

29/3  {AI05-0004-1} type Fast_Food_Queue is new Queue with record ...;
procedure Append(Q : in out Fast_Food_Queue; Person : in Person_Name);
procedure Remove_First(Q : in out Fast_Food_Queue; Person : out Person_Name);
function Cur_Count(Q : in Fast_Food_Queue) return Natural;
function Max_Count(Q : in Fast_Food_Queue) return Natural;

30/2  ...

31/2  Cashier, Counter : Fast_Food_Queue;

32/2  ...
    -- Add George (see 3.10.1) to the cashier's queue:
    Append (Cashier, George);
    -- After payment, move George to the sandwich counter queue:
    Transfer (Cashier, Counter);
    ...

```

33/2 An interface such as Queue can be used directly as the parent of a new type (as shown here), or can be used as a progenitor when a type is derived. In either case, the primitive operations of the interface are inherited. For Queue, the implementation of the four inherited routines must be provided. Inside the call of Transfer, calls will dispatch to the implementations of Append and Remove_First for type Fast_Food_Queue.

34/2 *{AI95-00433-01} Example of a task interface:*

```

35/2  type Serial_Device is task interface; -- see 9.1
procedure Read (Dev : in Serial_Device; C : out Character) is abstract;
procedure Write(Dev : in Serial_Device; C : in Character) is abstract;

```

36/2 The Serial_Device interface has two dispatching operations which are intended to be implemented by task entries (see 9.1).

Extensions to Ada 95

36.a/2 *{AI95-00251-01} {AI95-00345-01}* Interface types are new. They provide multiple inheritance of interfaces, similar to the facility provided in Java and other recent language designs.

Wording Changes from Ada 2005

{AI05-0070-1} **Correction:** Corrected the definition of elaboration for an `interface_type_definition` to match that of other type definitions. 36.b/3

3.10 Access Types

A value of an access type (an *access value*) provides indirect access to the object or subprogram it *designates*. Depending on its type, an access value can designate either subprograms, objects created by allocators (see 4.8), or more generally *aliased* objects of an appropriate type. 1

Discussion: A name *denotes* an entity; an access value *designates* an entity. The “dereference” of an access value X, written “X.all”, is a name that denotes the entity designated by X. 1.a

Language Design Principles

{AI05-0299-1} Access values should always be well defined (barring uses of certain unchecked features of Clause 13). In particular, uninitialized access variables should be prevented by compile-time rules. 1.b/3

Syntax

{AI95-00231-01} `access_type_definition ::=`
`[null_exclusion] access_to_object_definition`
`| [null_exclusion] access_to_subprogram_definition` 2/2

`access_to_object_definition ::=`
`access [general_access_modifier] subtype_indication` 3

`general_access_modifier ::= all | constant` 4

`access_to_subprogram_definition ::=`
`access [protected] procedure parameter_profile`
`| access [protected] function parameter_and_result_profile` 5

{AI95-00231-01} `null_exclusion ::= not null` 5.1/2

{AI95-00231-01} {AI95-00254-01} {AI95-00404-01} `access_definition ::=`
`[null_exclusion] access [constant] subtype_mark`
`| [null_exclusion] access [protected] procedure parameter_profile`
`| [null_exclusion] access [protected] function parameter_and_result_profile` 6/2

Static Semantics

{8652/0012} {AI95-00062-01} There are two kinds of access types, *access-to-object* types, whose values designate objects, and *access-to-subprogram* types, whose values designate subprograms. Associated with an access-to-object type is a *storage pool*; several access types may share the same storage pool. All descendants of an access type share the same storage pool. A storage pool is an area of storage used to hold dynamically allocated objects (called *pool elements*) created by allocators[; storage pools are described further in 13.11, “Storage Management”]. 7/1

Access-to-object types are further subdivided into *pool-specific* access types, whose values can designate only the elements of their associated storage pool, and *general* access types, whose values can designate the elements of any storage pool, as well as aliased objects created by declarations rather than allocators, and aliased subcomponents of other objects. 8

Implementation Note: The value of an access type will typically be a machine address. However, a value of a pool-specific access type can be represented as an offset (or index) relative to its storage pool, since it can point only to the elements of that pool. 8.a

{AI95-00225-01} {AI95-00363-01} {AI05-0053-1} {AI05-0142-4} {AI05-0277-1} A view of an object is defined to be *aliased* if it is defined by an `object_declaration`, `component_definition`, `parameter_specification`, or `extended_return_object_declaration` with the reserved word **aliased**, or by a renaming 9/3

of an aliased view. In addition, the dereference of an access-to-object value denotes an aliased view, as does a view conversion (see 4.6) of an aliased view. The current instance of an immutably limited type (see 7.5) is defined to be aliased. Finally, a formal parameter or generic formal object of a tagged type is defined to be aliased. [Aliased views are the ones that can be designated by an access value.]

- 9.a **Glossary entry:** An aliased view of an object is one that can be designated by an access value. Objects allocated by allocators are aliased. Objects can also be explicitly declared as aliased with the reserved word **aliased**. The Access attribute can be used to create an access value designating an aliased object.
- 9.b **Ramification:** The current instance of a nonlimited type is not aliased.
- 9.c The object created by an allocator is aliased, but not its subcomponents, except of course for those that themselves have **aliased** in their `component_definition`.
- 9.d The renaming of an aliased object is aliased.
- 9.e Slices are never aliased. See 4.1.2 for more discussion.
- 9.f/2 **Reason:** {A195-00225-01} The current instance of a limited type is defined to be aliased so that an access discriminant of a component can be initialized with T'Access inside the definition of T. Note that we don't want this to apply to a type that could become nonlimited later within its immediate scope, so we require the full definition to be limited.
- 9.g A formal parameter of a tagged type is defined to be aliased so that a (tagged) parameter X may be passed to an access parameter P by using P => X'Access. Access parameters are most important for tagged types because of dispatching-on-access-parameters (see 3.9.2). By restricting this to formal parameters, we minimize problems associated with allowing components that are not declared aliased to be pointed-to from within the same record.
- 9.h A view conversion of an aliased view is aliased so that the type of an access parameter can be changed without first converting to a named access type. For example:
- 9.i

```
type T1 is tagged ...;
procedure P(X : access T1);
```
- 9.j

```
type T2 is new T1 with ...;
procedure P(X : access T2) is
begin
  P(T1(X.all) 'Access); -- hand off to T1's P
  . . . -- now do extra T2-specific processing
end P;
```
- 9.k/2 *This paragraph was deleted.* {A195-00363-01}
- 9.l/2 We considered making more kinds of objects aliased by default. In particular, any object of a by-reference type will pretty much have to be allocated at an addressable location, so it can be passed by reference without using bit-field pointers. Therefore, one might wish to allow the Access and Unchecked_Access attributes for such objects. However, private parts are transparent to the definition of “by-reference type”, so if we made all objects of a by-reference type aliased, we would be violating the privacy of private parts. Instead, we would have to define a concept of “visibly by-reference” and base the rule on that. This seemed to complicate the rules more than it was worth, especially since there is no way to declare an untagged limited private type to be by-reference, since the full type might be nonlimited.
- 9.m **Discussion:** Note that we do not use the term “aliased” to refer to formal parameters that are referenced through multiple access paths (see 6.2).
- 10 An `access_to_object_definition` defines an access-to-object type and its first subtype; the `subtype_`-indication defines the *designated subtype* of the access type. If a `general_access_modifier` appears, then the access type is a general access type. If the modifier is the reserved word **constant**, then the type is an *access-to-constant type*[; a designated object cannot be updated through a value of such a type]. If the modifier is the reserved word **all**, then the type is an *access-to-variable type*[; a designated object can be both read and updated through a value of such a type]. If no `general_access_modifier` appears in the `access_to_object_definition`, the access type is a pool-specific access-to-variable type.
- 10.a **To be honest:** The type of the designated subtype is called the *designated type*.
- 10.b **Reason:** The modifier **all** was picked to suggest that values of a general access type could point into “all” storage pools, as well as to objects declared aliased, and that “all” access (both read and update) to the designated object was provided. We couldn't think of any use for pool-specific access-to-constant types, so any access type defined with the modifier **constant** is considered a general access type, and can point into any storage pool or at other (appropriate) aliased objects.
- 10.c **Implementation Note:** The predefined generic Unchecked_Deallocation can be instantiated for any named access-to-variable type. There is no (language-defined) support for deallocating objects designated by a value of an access-to-

constant type. Because of this, an allocator for an access-to-constant type can allocate out of a storage pool with no support for deallocation. Frequently, the allocation can be done at link-time, if the size and initial value are known then.

Discussion: For the purpose of generic formal type matching, the relevant subclasses of access types are access-to-subprogram types, access-to-constant types, and (named) access-to-variable types, with its subclass (named) general access-to-variable types. Pool-specific access-to-variable types are not a separately matchable subclass of types, since they don't have any "extra" operations relative to all (named) access-to-variable types. 10.d

An `access_to_subprogram_definition` defines an access-to-subprogram type and its first subtype; the `parameter_profile` or `parameter_and_result_profile` defines the *designated profile* of the access type. There is a *calling convention* associated with the designated profile[; only subprograms with this calling convention can be designated by values of the access type.] By default, the calling convention is "*protected*" if the reserved word **protected** appears, and "Ada" otherwise. [See Annex B for how to override this default.] 11

Ramification: The calling convention *protected* is in italics to emphasize that it cannot be specified explicitly by the user. This is a consequence of it being a reserved word. 11.a

Implementation Note: {AI95-00254-01} For a named access-to-subprogram type, the representation of an access value might include implementation-defined information needed to support up-level references — for example, a static link. The accessibility rules (see 3.10.2) ensure that in a "global-display-based" implementation model (as opposed to a static-link-based model), a named access-to-(unprotected)-subprogram value need consist only of the address of the subprogram. The global display is guaranteed to be properly set up any time the designated subprogram is called. Even in a static-link-based model, the only time a static link is definitely required is for an access-to-subprogram type declared in a scope nested at least two levels deep within subprogram or task bodies, since values of such a type might designate subprograms nested a smaller number of levels. For the normal case of a named access-to-subprogram type declared at the outermost (library) level, a code address by itself should be sufficient to represent the access value in many implementations. 11.b/2

For access-to-protected-subprogram, the access values will necessarily include both an address (or other identification) of the code of the subprogram, as well as the address of the associated protected object. This could be thought of as a static link, but it will be needed even for global-display-based implementation models. It corresponds to the value of the "implicit parameter" that is passed into every call of a protected operation, to identify the current instance of the protected type on which they are to operate. 11.c

Any `Elaboration_Check` is performed when a call is made through an access value, rather than when the access value is first "created" via a 'Access. For implementation models that normally put that check at the call-site, an access value will have to point to a separate entry point that does the check. Alternatively, the access value could point to a "subprogram descriptor" that consisted of two words (or perhaps more), the first being the address of the code, the second being the elaboration bit. Or perhaps more efficiently, just the address of the code, but using the trick that the descriptor is initialized to point to a Raise-Program-Error routine initially, and then set to point to the "real" code when the body is elaborated. 11.d

For implementations that share code between generic instantiations, the extra level of indirection suggested above to support `Elaboration_Checks` could also be used to provide a pointer to the per-instance data area normally required when calling shared code. The trick would be to put a pointer to the per-instance data area into the subprogram descriptor, and then make sure that the address of the subprogram descriptor is loaded into a "known" register whenever an indirect call is performed. Once inside the shared code, the address of the per-instance data area can be retrieved out of the subprogram descriptor, by indexing off the "known" register. 11.e

This paragraph was deleted. {AI95-00344-01} 11.f/2

{AI95-00254-01} Note that access parameters of an anonymous access-to-subprogram type are permitted. Such parameters represent full "downward" closures, meaning that in an implementation that uses a per-task (global) display, the display will have to be passed as a hidden parameter, and reconstructed at the point of call. 11.g/2

{AI95-00230-01} {AI95-00231-01} {AI95-00254-01} {AI05-0264-1} An `access_definition` defines an anonymous general access type or an anonymous access-to-subprogram type. For a general access type, the `subtype_mark` denotes its *designated subtype*; if the `general_access_modifier` **constant** appears, the type is an access-to-constant type; otherwise, it is an access-to-variable type. For an access-to-subprogram type, the `parameter_profile` or `parameter_and_result_profile` denotes its *designated profile*. 12/3

{AI95-00230-01} {AI95-00231-01} For each access type, there is a null access value designating no entity at all, which can be obtained by (implicitly) converting the literal **null** to the access type. [The null value of an access type is the default initial value of the type.] Nonnull values of an access-to-object type 13/2

are obtained by evaluating an `allocator`[], which returns an access value designating a newly created object (see 3.10.2)], or in the case of a general access-to-object type, evaluating an `attribute_reference` for the `Access` or `Unchecked_Access` attribute of an aliased view of an object. Nonnull values of an access-to-subprogram type are obtained by evaluating an `attribute_reference` for the `Access` attribute of a nonintrinsic subprogram.

- 13.a/2 *This paragraph was deleted.* {AI95-00231-01}
- 13.b/2 *This paragraph was deleted.* {AI95-00231-01}
- 13.1/2 {AI95-00231-01} A `null_exclusion` in a construct specifies that the null value does not belong to the access subtype defined by the construct, that is, the access subtype *excludes null*. In addition, the anonymous access subtype defined by the `access_definition` for a controlling access parameter (see 3.9.2) excludes null. Finally, for a `subtype_indication` without a `null_exclusion`, the subtype denoted by the `subtype_indication` excludes null if and only if the subtype denoted by the `subtype_mark` in the `subtype_indication` excludes null.
- 13.c/2 **Reason:** {AI95-00231-01} An `access_definition` used in a controlling parameter excludes null because it is necessary to read the tag to dispatch, and null has no tag. We would have preferred to require **not null** to be specified for such parameters, but that would have been too incompatible with Ada 95 code to require.
- 13.d/2 {AI95-00416-01} Note that we considered imposing a similar implicit null exclusion for controlling access results, but chose not to do that, because there is no Ada 95 compatibility issue, and there is no automatic null check inherent in the use of a controlling access result. If a null check is necessary, it is because there is a dereference of the result, or because the value is passed to a parameter whose subtype excludes null. If there is no dereference of the result, a null return value is perfectly acceptable, and can be a useful indication of a particular status of the call.
- 14/3 {8652/0013} {AI95-00012-01} {AI05-0264-1} [All subtypes of an access-to-subprogram type are constrained.] The first subtype of a type defined by an `access_definition` or an `access_to_object_definition` is unconstrained if the designated subtype is an unconstrained array or discriminated subtype; otherwise, it is constrained.
- 14.a **Proof:** The Legality Rules on `range_constraints` (see 3.5) do not permit the `subtype_mark` of the `subtype_indication` to denote an access-to-scalar type, only a scalar type. The Legality Rules on `index_constraints` (see 3.6.1) and `discriminant_constraints` (see 3.7.1) both permit access-to-composite types in a `subtype_indication` with such `_constraints`. Note that an access-to-access-to-composite is never permitted in a `subtype_indication` with a constraint.
- 14.b/2 **Reason:** {AI95-00363-01} Only `composite_constraints` are permitted for an access type, and only on access-to-composite types. A constraint on an access-to-scalar or access-to-access type might be violated due to assignments via other access paths that were not so constrained. By contrast, if the designated subtype is an array or discriminated type without defaults, the constraint could not be violated by unconstrained assignments, since array objects are always constrained, and discriminated objects are also constrained when the type does not have defaults for its discriminants. Constraints are not allowed on general access-to-unconstrained discriminated types if the type has defaults for its discriminants; constraints on pool-specific access types are usually allowed because allocated objects are usually constrained by their initial value.

Legality Rules

- 14.1/2 {AI95-00231-01} If a `subtype_indication`, `discriminant_specification`, `parameter_specification`, `parameter_and_result_profile`, `object_renaming_declaration`, or `formal_object_declaration` has a `null_exclusion`, the `subtype_mark` in that construct shall denote an access subtype that does not exclude null.
- 14.c/2 **To be honest:** {AI95-00231-01} This means “directly allowed in”; we are not talking about a `null_exclusion` that occurs in an `access_definition` in one of these constructs (for an `access_definition`, the `subtype_mark` in such an `access_definition` is not restricted).
- 14.d/2 **Reason:** {AI95-00231-01} This is similar to doubly constraining a composite subtype, which we also don't allow.

Dynamic Semantics

- 15/2 {AI95-00231-01} A `composite_constraint` is *compatible* with an unconstrained access subtype if it is compatible with the designated subtype. A `null_exclusion` is compatible with any access subtype that does not exclude null. An access value *satisfies* a `composite_constraint` of an access subtype if it equals

the null value of its type or if it designates an object whose value satisfies the constraint. An access value satisfies an exclusion of the null value if it does not equal the null value of its type.

The elaboration of an `access_type_definition` creates the access type and its first subtype. For an access-to-object type, this elaboration includes the elaboration of the `subtype_indication`, which creates the designated subtype. 16

{AI95-00230-01} {AI95-00254-01} The elaboration of an `access_definition` creates an anonymous access type. 17/2

NOTES

83 Access values are called “pointers” or “references” in some other languages. 18

84 Each access-to-object type has an associated storage pool; several access types can share the same pool. An object can be created in the storage pool of an access type by an `allocator` (see 4.8) for the access type. A storage pool (roughly) corresponds to what some other languages call a “heap.” See 13.11 for a discussion of pools. 19

85 Only `index_constraints` and `discriminant_constraints` can be applied to access types (see 3.6.1 and 3.7.1). 20

Examples

Examples of access-to-object types: 21

```
{AI95-00433-01} type Peripheral_Ref is not null access Peripheral; -- see 3.8.1
type Binop_Ptr is access all Binary_Operation'Class;
-- general access-to-class-wide, see 3.9.1
```

22/2

Example of an access subtype: 23

```
subtype Drum_Ref is Peripheral_Ref(Drum); -- see 3.8.1
```

24

Example of an access-to-subprogram type: 25

```
type Message_Procedure is access procedure (M : in String := "Error!");
procedure Default_Message_Procedure(M : in String);
Give_Message : Message_Procedure := Default_Message_Procedure'Access;
...
procedure Other_Procedure(M : in String);
...
Give_Message := Other_Procedure'Access;
...
Give_Message("File not found."); -- call with parameter (.all is optional)
Give_Message.all; -- call with no parameters
```

26

Extensions to Ada 83

The syntax for `access_type_definition` is changed to support general access types (including access-to-constants) and access-to-subprograms. The syntax rules for `general_access_modifier` and `access_definition` are new. 26.a

Wording Changes from Ada 83

{AI05-0190-1} We use the term “storage pool” to talk about the data area from which allocation takes place. The term “collection” is only used for finalization. (“Collection” and “storage pool” are not the same thing because multiple unrelated access types can share the same storage pool; see 13.11 for more discussion.) 26.b/3

Inconsistencies With Ada 95

{AI95-00231-01} Access discriminants and noncontrolling access parameters no longer exclude null. A program which passed `null` to such an access discriminant or access parameter and expected it to raise `Constraint_Error` may fail when compiled with Ada 2005. One hopes that there no such programs outside of the ACATS. (Of course, a program which actually wants to pass `null` will work, which is far more likely.) 26.c/2

{AI95-00363-01} Most unconstrained aliased objects with defaulted discriminants are no longer constrained by their initial values. This means that a program that raised `Constraint_Error` from an attempt to change the discriminants will no longer do so. The change only affects programs that depended on the raising of `Constraint_Error` in this case, so the inconsistency is unlikely to occur outside of the ACATS. This change may however cause compilers to implement these objects differently, possibly taking additional memory or time. This is unlikely to be worse than the differences caused by any major compiler upgrade. 26.d/2

Incompatibilities With Ada 95

- 26.e/2 {AI95-00225-01} **Amendment Correction:** The rule defining when a current instance of a limited type is considered to be aliased has been tightened to apply only to types that cannot become nonlimited. A program that attempts to take 'Access of the current instance of a limited type that can become nonlimited will be illegal in Ada 2005. While original Ada 95 allowed the current instance of any limited type to be treated as aliased, this was inconsistently implemented in compilers, and was likely to not work as expected for types that are ultimately nonlimited.

Extensions to Ada 95

- 26.f/2 {AI95-00231-01} The `null_exclusion` is new. It can be used in both anonymous and named access type definitions. It is most useful to declare that parameters cannot be **null**, thus eliminating the need for checks on use.
- 26.g/2 {AI95-00231-01} {AI95-00254-01} {AI95-00404-01} The kinds of anonymous access types allowed were increased by adding anonymous access-to-constant and anonymous access-to-subprogram types. Anonymous access-to-subprogram types used as parameters allow passing of subprograms at any level.

Wording Changes from Ada 95

- 26.h/2 {8652/0012} {AI95-00062-01} **Corrigendum:** Added accidentally-omitted wording that says that a derived access type shares its storage pool with its parent type. This was clearly intended, both because of a note in 3.4, and because anything else would have been incompatible with Ada 83.
- 26.i/2 {8652/0013} {AI95-00012-01} **Corrigendum:** Fixed typographical errors in the description of when access types are constrained.
- 26.j/2 {AI95-00230-01} The wording was fixed to allow **allocators** and the literal **null** for anonymous access types. The former was clearly intended by Ada 95; see the Implementation Advice in 13.11.
- 26.k/2 {AI95-00363-01} The rules about aliased objects being constrained by their initial values now apply only to allocated objects, and thus have been moved to 4.8, “Allocators”.

Wording Changes from Ada 2005

- 26.l/3 {AI05-0053-1} {AI05-0277-1} **Correction:** The rule about a current instance being aliased now is worded in terms of immutably limited types. Wording was also added to make extended return object declarations that have the keyword **aliased** be considered aliased. This latter was a significant oversight in Ada 2005 — technically, the keyword **aliased** had no effect. But of course implementations followed the intent, not the letter of the Standard.
- 26.m/3 {AI05-0142-4} Explicitly aliased parameters (see 6.1) are defined to be aliased.

3.10.1 Incomplete Type Declarations

- 1 There are no particular limitations on the designated type of an access type. In particular, the type of a component of the designated type can be another access type, or even the same access type. This permits mutually dependent and recursive access types. An `incomplete_type_declaration` can be used to introduce a type to be used as a designated type, while deferring its full definition to a subsequent `full_type_declaration`.

Syntax

- 2/2 {AI95-00326-01} `incomplete_type_declaration ::=`
`type defining_identifier [discriminant_part] [is tagged];`

Static Semantics

- 2.1/2 {AI95-00326-01} An `incomplete_type_declaration` declares an *incomplete view* of a type and its first subtype; the first subtype is unconstrained if a `discriminant_part` appears. If the `incomplete_type_declaration` includes the reserved word **tagged**, it declares a *tagged incomplete view*. [An incomplete view of a type is a limited view of the type (see 7.5).]
- 2.2/2 {AI95-00326-01} Given an access type *A* whose designated type *T* is an incomplete view, a dereference of a value of type *A* also has this incomplete view except when:

- Discussion:** *{AI05-0208-1}* Whether the designated type is an incomplete view (and thus whether this set of rules applies) is determined by the view of the type at the declaration of the access type; it does not change during the life of the type. 2.a/3
- it occurs within the immediate scope of the completion of *T*, or 2.3/2
 - *{AI05-0208-1}* it occurs within the scope of a `nonlimited_with_clause` that mentions a library package in whose visible part the completion of *T* is declared, or 2.4/3
 - *{AI05-0208-1}* it occurs within the scope of the completion of *T* and *T* is an incomplete view declared by an `incomplete_type_declaration`. 2.5/3
- {AI05-0162-1}* In these cases, the dereference has the view of *T* visible at the point of the dereference. 2.6/3
- Discussion:** We need the “in whose visible part” rule so that the second rule doesn't trigger in the body of a package with a `with` of a child unit: 2.b/2
- ```

package P is
private
 type T;
 type PtrT is access T;
end P;

private package P.C is
 Ptr : PtrT;
end P.C;

{AI05-0005-1} with P.C;
package body P is
 -- Ptr.all'Size is not legal here, but we are within the scope
 -- of a nonlimited_with_clause for P.
 type T is ...
 -- Ptr.all'Size is legal here.
end P;

```
- 2.c/2
- 2.d/2
- 2.e/3
- {AI95-00412-01}* *{AI05-0162-1}* *{AI05-0208-1}* Similarly, if a `subtype_mark` denotes a `subtype_declaration` defining a subtype of an incomplete view *T*, the `subtype_mark` denotes an incomplete view except under the same three circumstances given above, in which case it denotes the view of *T* visible at the point of the `subtype_mark`. 2.7/3

#### Legality Rules

- {AI05-0162-1}* An `incomplete_type_declaration` requires a completion, which shall be a `type_declaration` other than an `incomplete_type_declaration`. [If the `incomplete_type_declaration` occurs immediately within either the visible part of a `package_specification` or a `declarative_part`, then the `type_declaration` shall occur later and immediately within this visible part or `declarative_part`. If the `incomplete_type_declaration` occurs immediately within the private part of a given `package_specification`, then the `type_declaration` shall occur later and immediately within either the private part itself, or the `declarative_part` of the corresponding `package_body`.] 3/3
- Proof:** This is implied by the next AARM-only rule, plus the rules in 3.11.1, “Completions of Declarations” which require a completion to appear later and immediately within the same declarative region. 3.a
- To be honest:** If the `incomplete_type_declaration` occurs immediately within the visible part of a `package_specification`, then the completing `type_declaration` shall occur immediately within this visible part. 3.b
- To be honest:** If the implementation supports it, an `incomplete_type_declaration` can be imported (using aspect `Import`, see B.1), in which case no explicit completion is allowed. 3.c
- {AI95-00326-01}* *{AI05-0162-1}* If an `incomplete_type_declaration` includes the reserved word **tagged**, then a `type_declaration` that completes it shall declare a tagged type. If an `incomplete_type_declaration` has a `known_discriminant_part`, then a `type_declaration` that completes it shall have a fully conforming (explicit) `known_discriminant_part` (see 6.3.1). [If an `incomplete_type_declaration` has no `discriminant_part` (or an `unknown_discriminant_part`), then a corresponding `type_declaration` is nevertheless allowed to have discriminants, either explicitly, or inherited via derivation.] 4/3

- 5/2 {AI95-00326-01} A name that denotes an incomplete view of a type may be used as follows:
- 6/3
- {AI05-0098-1} as the `subtype_mark` in the `subtype_indication` of an `access_to_object_definition`; [the only form of constraint allowed in this `subtype_indication` is a `discriminant_constraint` [(a `null_exclusion` is not allowed)];]
- 6.a **Implementation Note:** We now allow `discriminant_constraints` even if the full type is deferred to the package body. However, there is no particular implementation burden because we have dropped the concept of the dependent compatibility check. In other words, we have effectively repealed AI83-00007.
- 7/2
- {AI95-00326-01} {AI95-00412-01} as the `subtype_mark` in the `subtype_indication` of a `subtype_declaration`; the `subtype_indication` shall not have a `null_exclusion` or a `constraint`;
- 8/3
- {AI95-00326-01} {AI05-0151-1} as the `subtype_mark` in an `access_definition` for an access-to-object type;
- 8.a/2 **To be honest:** This does not mean any random `subtype_mark` in a construct that makes up an `access_definition`, such as a `formal_part`, just the one given directly in the syntax of `access_definition`.
- 8.1/3
- {AI05-0151-1} as the `subtype_mark` defining the subtype of a parameter or result in a profile occurring within a `basic_declaration`;
- 8.b/3 **Ramification:** But not in the profile for a body or entry.
- 8.2/3
- {AI05-0213-1} as a generic actual parameter whose corresponding generic formal parameter is a formal incomplete type (see 12.5.1).
- 8.3/2 {AI95-00326-01} If such a name denotes a tagged incomplete view, it may also be used:
- 8.4/3
- {AI95-00326-01} {AI05-0151-1} as the `subtype_mark` defining the subtype of a parameter in the profile for a `subprogram_body`, `entry_body`, or `accept_statement`;
- 9/2
- {AI95-00326-01} as the `prefix` of an `attribute_reference` whose `attribute_designator` is `Class`; such an `attribute_reference` is restricted to the uses allowed here; it denotes a tagged incomplete view.
- 9.a/2 *This paragraph was deleted.* {AI95-00326-01}
- 9.1/3 *This paragraph was deleted.* {AI95-00326-01} {AI05-0151-1}
- 9.2/3
- *This paragraph was deleted.* {AI95-00326-01} {AI05-0098-1} {AI05-0151-1}
- 9.b/3 *This paragraph was deleted.*
- 9.3/2 {AI95-00326-01} If any of the above uses occurs as part of the declaration of a primitive subprogram of the incomplete view, and the declaration occurs immediately within the private part of a package, then the completion of the incomplete view shall also occur immediately within the private part; it shall not be deferred to the package body.
- 9.c/2 **Reason:** This fixes a hole in Ada 95 where a dispatching operation with an access parameter could be declared in a private part and a dispatching call on it could occur in a child even though there is no visibility on the full type, requiring access to the controlling tag without access to the representation of the type.
- 9.4/2 {AI95-00326-01} No other uses of a name that denotes an incomplete view of a type are allowed.
- 10/3 {AI95-00326-01} {AI05-0151-1} A `prefix` that denotes an object shall not be of an incomplete view. An actual parameter in a call shall not be of an untagged incomplete view. The result object of a function call shall not be of an incomplete view. A `prefix` shall not denote a subprogram having a formal parameter of an untagged incomplete view, nor a return type that is an incomplete view.
- 10.a/2 **Reason:** We used to disallow all dereferences of an incomplete type. Now we only disallow such dereferences when used as a `prefix`. Dereferences used in other contexts do not pose a problem since normal type matching will preclude their use except when the full type is “nearby” as context (for example, as the expected type).
- 10.b/2 This also disallows `prefixes` that are directly of an incomplete view. For instance, a parameter *P* can be declared of a tagged incomplete type, but we don't want to allow *P'Size*, *P'Alignment*, or the like, as representation values aren't known for an incomplete view.

We say “denotes an object” so that prefixes that directly name an incomplete view are not covered; the previous rules cover such cases, and we certainly don't want to ban Incomp'Class. 10.c/2

{AI05-0151-1} As subprogram profiles now may include any kind of incomplete type, we also disallow passing objects of untagged incomplete types in subprogram calls (as the parameter passing method is not known as it is for tagged types) and disallow returning any sort of incomplete objects (since we don't know how big they are). 10.d/3

*Paragraph 11 was deleted.*

#### Dynamic Semantics

The elaboration of an `incomplete_type_declaration` has no effect. 12

**Reason:** An incomplete type has no real existence, so it doesn't need to be "created" in the usual sense we do for other types. It is roughly equivalent to a "forward;" declaration in Pascal. Private types are different, because they have a different set of characteristics from their full type. 12.a

#### NOTES

86 Within a `declarative_part`, an `incomplete_type_declaration` and a corresponding `full_type_declaration` cannot be separated by an intervening body. This is because a type has to be completely defined before it is frozen, and a body freezes all types declared prior to it in the same `declarative_part` (see 13.14). 13

87 {AI05-0151-1} {AI05-0269-1} A name that denotes an object of an incomplete view is defined to be of a limited type. Hence, the target of an assignment statement cannot be of an incomplete view. 13.1/3

#### Examples

*Example of a recursive type:* 14

```

type Cell; -- incomplete type declaration 15
type Link is access Cell;
type Cell is 16
 record
 Value : Integer;
 Succ : Link;
 Pred : Link;
 end record;
Head : Link := new Cell'(0, null, null); 17
Next : Link := Head.Succ;

```

*Examples of mutually dependent access types:* 18

```

{AI95-00433-01} type Person(<>); -- incomplete type declaration 19/2
type Car is tagged; -- incomplete type declaration
{AI95-00433-01} type Person_Name is access Person; 20/2
type Car_Name is access all Car'Class;
{AI95-00433-01} type Car is tagged 21/2
 record
 Number : Integer;
 Owner : Person_Name;
 end record;
type Person(Sex : Gender) is 22
 record
 Name : String(1 .. 20);
 Birth : Date;
 Age : Integer range 0 .. 130;
 Vehicle : Car_Name;
 case Sex is
 when M => Wife : Person_Name(Sex => F);
 when F => Husband : Person_Name(Sex => M);
 end case;

George : Person_Name := new Person(M);
...
George.Vehicle := Your_Car;

```

*Extensions to Ada 83*

- 23.a The `full_type_declaration` that completes an `incomplete_type_declaration` may have a `known_discriminant_part` even if the `incomplete_type_declaration` does not.
- 23.b/1 A `discriminant_constraint` may be applied to an incomplete type, even if its completion is deferred to the package body, because there is no “dependent compatibility check” required any more. Of course, the constraint can be specified only if a `known_discriminant_part` was given in the `incomplete_type_declaration`. As mentioned in the previous paragraph, that is no longer required even when the full type has discriminants.

*Wording Changes from Ada 83*

- 23.c Dereferences producing incomplete types were not explicitly disallowed in RM83, though AI83-00039 indicated that it was not strictly necessary since troublesome cases would result in `Constraint_Error` at run time, since the access value would necessarily be null. However, this introduces an undesirable implementation burden, as illustrated by Example 4 of AI83-00039:
- 23.d
- ```
package Pack is
  type Pri is private;
private
  type Sep;
  type Pri is access Sep;
  X : Pri;
end Pack;
```
- 23.e
- ```
package body Pack is -- Could be separately compiled!
 type Sep is ...;
 X := new Sep;
end Pack;
```
- 23.f
- ```
pragma Elaborate(Pack);
private package Pack.Child is
  I : Integer := X.all'Size; -- Legal, by AI-00039.
end Pack.Child;
```
- 23.g Generating code for the above example could be a serious implementation burden, since it would require all aliased objects to store size dope, and for that dope to be in the same format for all kinds of types (or some other equivalently inefficient implementation). On the contrary, most implementations allocate dope differently (or not at all) for different designated subtypes.

Incompatibilities With Ada 95

- 23.h/2 {AI95-00326-01} It is now illegal to use an incomplete view (type) as the parameter or result of an access-to-subprogram type unless the incomplete view is completed in the same declaration list as the use. This was allowed in Ada 95 for incomplete types where the completion was deferred to the body. By disallowing this rare use of incomplete views, we can allow the use of incomplete views in many more places, which is especially valuable for limited views.
- 23.i/2 {AI95-00326-01} It is now illegal to use an incomplete view (type) in a primitive subprogram of the type unless the incomplete view is completed in the package specification. This was allowed in Ada 95 for incomplete types where the completion was deferred to the body (the use would have to be in an access parameter). This incompatibility was caused by the fix for the hole noted in Legality Rules above.

Extensions to Ada 95

- 23.j/2 {AI95-00326-01} Tagged incomplete types are new. They are allowed in parameter declarations as well as the usual places, as tagged types are always by-reference types (and thus there can be no code generation issue).
- 23.k/2 {AI95-00412-01} A `subtype_declaration` can be used to give a new name to an incomplete view of a type. This is valuable to give shorter names to entities imported with a `limited_with_clause`.

Wording Changes from Ada 95

- 23.l/2 {AI95-00326-01} The description of incomplete types as *incomplete views* is new. Ada 95 defined these as separate types, but neglected to give any rules for matching them with other types. Luckily, implementers did the right thing anyway. This change also makes it easier to describe the meaning of a limited view.

Extensions to Ada 2005

- 23.m/3 {AI05-0098-1} **Correction:** Fixed the definition so that an anonymous access-to-subprogram type can use an incomplete view in the same way that a named access-to-subprogram type can.

{AI05-0151-1} Incomplete types now can be used in subprogram declarations. The type has to be complete before any calls or the body is declared. This reduces the places where access types are required for types imported from limited views of packages. 23.n/3

{AI05-0162-1} Incomplete types now can be completed by private types and private extensions. Since this can already happen for limited views, there is no remaining reason to disallow it for explicitly declared incomplete types. 23.o/3

Wording Changes from Ada 2005

{AI05-0208-1} **Correction:** Changed the rules of uses of dereferences of incomplete views such that it does not introduce an unintentional incompatibility with Ada 83 and Ada 95. 23.p/3

{AI05-0213-1} Incomplete types now can be used as actuals to formal incomplete types (see 12.5.1). 23.q/3

3.10.2 Operations of Access Types

{AI05-0299-1} [The attribute `Access` is used to create access values designating aliased objects and nonintrinsic subprograms. The “accessibility” rules prevent dangling references (in the absence of uses of certain unchecked features — see Clause 13).] 1/3

Language Design Principles

It should be possible for an access value to designate an object declared by an object declaration, or a subcomponent thereof. In implementation terms, this means pointing at stack-allocated and statically allocated data structures. However, dangling references should be prevented, primarily via compile-time rules, so long as features like `Unchecked_Access` and `Unchecked_Deallocation` are not used. 1.a

In order to create such access values, we require that the access type be a general access type, that the designated object be aliased, and that the accessibility rules be obeyed. 1.b

Name Resolution Rules

{AI95-00235-01} For an `attribute_reference` with `attribute_designator` `Access` (or `Unchecked_Access` — see 13.10), the expected type shall be a single access type *A* such that: 2/2

- {AI95-00235-01} *A* is an access-to-object type with designated type *D* and the type of the prefix is *D*'Class or is covered by *D*, or 2.1/2
- {AI95-00235-01} *A* is an access-to-subprogram type whose designated profile is type conformant with that of the prefix. 2.2/2

{AI95-00235-01} [The prefix of such an `attribute_reference` is never interpreted as an `implicit_dereference` or a `parameterless_function_call` (see 4.1.4).] The designated type or profile of the expected type of the `attribute_reference` is the expected type or profile for the prefix. 2.3/2

Discussion: Saying that the expected type shall be a “single access type” is our “new” way of saying that the type has to be determinable from context using only the fact that it is an access type. See 4.2 and 8.6. Specifying the expected profile only implies type conformance. The more stringent subtype conformance is required by a Legality Rule. This is the only Resolution Rule that applies to the name in a prefix of an `attribute_reference`. In all other cases, the name has to be resolved without using context. See 4.1.4. 2.a

{AI95-00235-01} Saying “single access type” is a bit of a fudge. Both the context and the prefix may provide both multiple types; “single” only means that a single, specific interpretation must remain after resolution. We say “single” here to trigger the Legality Rules of 8.6. The resolution of an access attribute is similar to that of an `assignment_statement`. For example: 2.b/2

```
type Int_Ptr is access all Integer;
type Char_Ptr is access all Character;
type Float_Ptr is access all Float; 2.c/2
```

```
function Zap (Val : Int_Ptr) return Float; -- (1)
function Zap (Val : Float_Ptr) return Float; -- (2)
function Zop return Int_Ptr; -- (3)
function Zop return Char_Ptr; -- (4) 2.d/2
```

```
Result : Float := Zap (Zop.all'Access); -- Resolves to Zap (1) and Zop (3). 2.e/2
```

3/2 {AI95-00162-01} [The accessibility rules, which prevent dangling references, are written in terms of *accessibility levels*, which reflect the run-time nesting of *masters*. As explained in 7.6.1, a master is the execution of a certain construct, such as a `subprogram_body`. An accessibility level is *deeper than* another if it is more deeply nested at run time. For example, an object declared local to a called subprogram has a deeper accessibility level than an object declared local to the calling subprogram. The accessibility rules for access types require that the accessibility level of an object designated by an access value be no deeper than that of the access type. This ensures that the object will live at least as long as the access type, which in turn ensures that the access value cannot later designate an object that no longer exists. The `Unchecked_Access` attribute may be used to circumvent the accessibility rules.]

3.a/3 **Discussion:** {AI05-0005-1} The `Unchecked_Access` attribute acts as if the object was declared at library-level; this applies even when it is used as the value of anonymous access type. See 13.10.

3.b/3 Subclause 3.10.2, home of the accessibility rules, is informally known as the “Heart of Darkness” amongst the maintainers of Ada. Woe unto all who enter here (well, at least unto anyone that needs to understand any of these rules).

4 [A given accessibility level is said to be *statically deeper* than another if the given level is known at compile time (as defined below) to be deeper than the other for all possible executions. In most cases, accessibility is enforced at compile time by Legality Rules. Run-time accessibility checks are also used, since the Legality Rules do not cover certain cases involving access parameters and generic packages.]

5 Each master, and each entity and view created by it, has an accessibility level:

6 • The accessibility level of a given master is deeper than that of each dynamically enclosing master, and deeper than that of each master upon which the task executing the given master directly depends (see 9.3).

7/3 • {AI95-00162-01} {AI95-00416-01} {AI05-0235-1} An entity or view defined by a declaration and created as part of its elaboration has the same accessibility level as the innermost master of the declaration except in the cases of renaming and derived access types described below. Other than for an explicitly aliased parameter, a formal parameter of a callable entity has the same accessibility level as the master representing the invocation of the entity.

7.a/2 **Reason:** {AI95-00416-01} This rule defines the “normal” accessibility of entities. In the absence of special rules below, we intend for this rule to apply.

7.b/2 **Discussion:** {AI95-00416-01} This rule defines the accessibility of all named access types, as well as the accessibility level of all anonymous access types other than those for access parameters and access discriminants. Special rules exist for the accessibility level of such anonymous types. Components, stand-alone objects, and function results whose (anonymous) type is defined by an `access_definition` have accessibility levels corresponding to named access types defined at the same point.

7.c/2 **Ramification:** {AI95-00230-01} Because accessibility level is determined by where the `access_definition` is elaborated, for a type extension, the anonymous access types of components (other than access discriminants) inherited from the parent have the same accessibility as they did in the parent; those in the extension part have the accessibility determined by the scope where the type extension is declared. Similarly, the types of the nondiscriminant access components of a derived untagged type have the same accessibility as they did in the parent.

7.d/3 **To be honest:** {AI05-0235-1} We use “invocation of” in the parameter case as a master is formally an execution of something. But we mean this to be interpreted statically (for instance, as the body of the subprogram) for the purposes of computing “statically deeper than” (see below).

7.e/3 **Ramification:** {AI05-0235-1} Note that accessibility can differ depending on the view of an object (for both static and dynamic accessibility). For instance, the accessibility level of a formal parameter may be different than the accessibility level of the corresponding actual parameter. This occurs in other cases as well.

7.f/3 **Reason:** {AI05-0235-1} We define the (dynamic) accessibility of formal parameters in order that it does not depend on the parameter passing model (by-reference or by-copy) as that is implementation defined. Otherwise, there would be a portability issue.

8 • The accessibility level of a view of an object or subprogram defined by a `renaming_declaration` is the same as that of the renamed view.

- {AI95-00416-01} The accessibility level of a view conversion, `qualified_expression`, or parenthesized expression, is the same as that of the operand. 9/2
- {AI05-0188-1} The accessibility level of a `conditional_expression` is the accessibility level of the evaluated `dependent_expression`. 9.1/3
- {AI95-00318-02} {AI95-00416-01} {AI05-0234-1} The accessibility level of an aggregate that is used (in its entirety) to directly initialize part of an object is that of the object being initialized. In other contexts, the accessibility level of an aggregate is that of the innermost master that evaluates the aggregate. 10/3
- {AI05-0234-1} The accessibility level of the result of a function call is that of the *master of the function call*, which is determined by the point of call as follows: 10.1/3
 - If the result is used (in its entirety) to directly initialize part of an object, the master is that of the object being initialized. In the case where the initialized object is a coextension (see below) that becomes a coextension of another object, the master is that of the eventual object to which the coextension will be transferred. 10.2/3

To be honest: {AI95-00416-01} The first sentence is talking about a static use of the entire return object — a slice that happens to be the entire return object doesn't count. On the other hand, this is intended to allow parentheses and `qualified_expressions`. 10.a/2

Ramification: {AI95-00416-01} {AI05-0234-1} If the function is used as a prefix, this bullet does not apply. Similarly, an `assignment_statement` is not an initialization of an object, so this bullet does not apply. 10.b/3
 - If the result is of an anonymous access type and is the operand of an explicit conversion, the master is that of the target type of the conversion; 10.3/3
 - If the result is of an anonymous access type and defines an access discriminant, the master is the same as that for an object created by an anonymous allocator that defines an access discriminant (even if the access result is of an access-to-subprogram type). 10.4/3
 - If the call itself defines the result of a function to which one of the above rules applies, these rules are applied recursively; 10.5/3
 - In other cases, the master of the call is that of the innermost master that evaluates the function call. 10.6/3

Ramification: {AI95-00318-02} {AI95-00416-01} The “innermost master which evaluated the function call” does not include the function call itself (which might be a master). 10.c/2

{AI95-00318-02} {AI95-00416-01} We really mean the innermost master here, which could be a very short lifetime. Consider a function call used as a parameter of a procedure call. In this case the innermost master which evaluated the function call is the procedure call. 10.d/2

Ramification: {AI05-0234-1} These rules do not mention whether the result object is built-in-place (see 7.6). In particular, in the case where building in place is optional, the choice whether or not to build-in-place has no effect on masters, lifetimes, or accessibility. 10.d.1/3

Implementation Note: {AI05-0234-1} There are several cases where the implementation may have to pass in the accessibility level of the result object on a call, to support later rules where the accessibility level comes from the master of the call: 10.d.2/3

 - when the function result may have a part with access discriminants; 10.d.3/3
 - when the function result type is an anonymous access type; 10.d.4/3
 - when the function result is built-in-place; 10.d.5/3
 - when the function has an explicitly aliased parameter. 10.d.6/3

In particular, this implies passing a level parameter when the result type is class-wide, since descendants may add access discriminants. For most implementations this will mean that functions with controlling results will also need a level parameter. 10.d.7/3
- {AI05-0284-1} In the case of a call to a function whose result type is an anonymous access type, the accessibility level of the type of the result of the function call is also determined by the point of call as described above. 10.7/3

- 10.8/3 • *{AI95-00416-01}* Within a return statement, the accessibility level of the return object is that of the execution of the return statement. If the return statement completes normally by returning from the function, then prior to leaving the function, the accessibility level of the return object changes to be a level determined by the point of call, as does the level of any coextensions (see below) of the return object.
- 10.e/2 **Reason:** We define the accessibility level of the return object during the return statement to be that of the return statement itself so that the object may be designated by objects local to the return statement, but not by objects outside the return statement. In addition, the intent is that the return object gets finalized if the return statement ends without actually returning (for example, due to propagating an exception, or a goto). For a normal return, of course, no finalization is done before returning.
- 11 • The accessibility level of a derived access type is the same as that of its ultimate ancestor.
- 11.1/2 • *{AI95-00230-01}* The accessibility level of the anonymous access type defined by an `access_definition` of an `object_renaming_declaration` is the same as that of the renamed view.
- 12/2 • *{AI95-00230-01}* *{AI95-00416-01}* The accessibility level of the anonymous access type of an access discriminant in the `subtype_indication` or `qualified_expression` of an `allocator`, or in the `expression` or `return_subtype_indication` of a return statement is determined as follows:
 - 12.1/2 • If the value of the access discriminant is determined by a `discriminant_association` in a `subtype_indication`, the accessibility level of the object or subprogram designated by the associated value (or library level if the value is null);
- 12.a/2 **Discussion:** This deals with the following cases, when they occur in the context of an `allocator` or return statement:
 - 12.b/2 • An `extension_aggregate` where the `ancestor_part` is a `subtype_mark` denoting a constrained subtype;
 - 12.c/2 • An uninitialized `allocator` where the `subtype_indication` defines a constrained subtype;
 - 12.d/2 • A discriminant of an object with a constrained nominal subtype, including constrained components, the result of calling a function with a constrained result subtype, the dereference of an access-to-constrained subtype, etc.
- 12.e/3 **Ramification:** *{AI05-0281-1}* The `subtype_indication` mentioned in this bullet is not necessarily the one given in the `allocator` or return statement that is determining the accessibility level; the constrained subtype might have been defined in an earlier declaration (as a named subtype).
- 12.f/3 *{AI05-0005-1}* If the value for this rule and the next one is derived from an `Unchecked_Access` attribute, the accessibility is library-level no matter what the accessibility level of the object is (see 13.10).
- 12.2/3 • *{AI05-0234-1}* If the value of the access discriminant is determined by a `default_expression` in the declaration of the discriminant, the level of the object or subprogram designated by the associated value (or library level if null);
- 12.f.1/3 **Discussion:** This covers the case of an unconstrained subcomponent of a limited type with defaulted access discriminants.
- 12.3/3 • *{AI05-0004-1}* If the value of the access discriminant is determined by a `record_component_association` in an `aggregate`, the accessibility level of the object or subprogram designated by the associated value (or library level if the value is null);
- 12.g/2 **Discussion:** In this bullet, the `aggregate` has to occur in the context of an `allocator` or return statement, while the `subtype_indication` of the previous bullet can occur anywhere (it doesn't have to be directly given in the `allocator` or return statement).
- 12.4/3 • In other cases, where the value of the access discriminant is determined by an object with an unconstrained nominal subtype, the accessibility level of the object.
- 12.h/2 **Discussion:** *{AI95-00416-01}* In other words, if you know the value of the discriminant for an `allocator` or return statement from a discriminant constraint or an `aggregate` component association, then that determines the accessibility level; if you don't know it, then it is based on the object itself.
- 12.5/3 • *{AI95-00416-01}* The accessibility level of the anonymous access type of an access discriminant in any other context is that of the enclosing object.

- $\{AI95-00162-01\}$ $\{AI95-00254-01\}$ $\{AI05-0270-1\}$ The accessibility level of the anonymous access type of an access parameter specifying an access-to-object type is the same as that of the view designated by the actual (or library-level if the actual is null). 13/3

Ramification: $\{AI05-0005-1\}$ If the value of the actual is derived from an `Unchecked_Access` attribute, the accessibility is always library-level (see 13.10). 13.a/3
- $\{AI95-00254-01\}$ The accessibility level of the anonymous access type of an access parameter specifying an access-to-subprogram type is deeper than that of any master; all such anonymous access types have this same level. 13.1/2

Reason: These represent “downward closures” and thus require passing of static links or global display information (along with generic sharing information if the implementation does sharing) along with the address of the subprogram. We must prevent conversions of these to types with “normal” accessibility, as those typically don't include the extra information needed to make a call. 13.b/2
- $\{AI05-0148-1\}$ $\{AI05-0240-1\}$ The accessibility level of the type of a stand-alone object of an anonymous access-to-object type is the same as the accessibility level of the type of the access value most recently assigned to the object[; accessibility checks ensure that this is never deeper than that of the declaration of the stand-alone object]. 13.2/3
- $\{AI05-0142-4\}$ $\{AI05-0240-1\}$ The accessibility level of an explicitly aliased (see 6.1) formal parameter in a function body is determined by the point of call; it is the same level that the return object ultimately will have. 13.3/3
- $\{AI95-00416-01\}$ $\{AI05-0051-1\}$ $\{AI05-0253-1\}$ The accessibility level of an object created by an `allocator` is the same as that of the access type, except for an `allocator` of an anonymous access type (an *anonymous allocator*) in certain contexts, as follows: For an anonymous allocator that defines the result of a function with an access result, the accessibility level is determined as though the `allocator` were in place of the call of the function; in the special case of a call that is the operand of a type conversion, the level is that of the target access type of the conversion. For an anonymous allocator defining the value of an access parameter, the accessibility level is that of the innermost master of the call. For an anonymous allocator whose type is that of a stand-alone object of an anonymous access-to-object type, the accessibility level is that of the declaration of the stand-alone object. For one defining an access discriminant, the accessibility level is determined as follows: 14/3

 - $\{AI95-00416-01\}$ $\{AI05-0024-1\}$ for an `allocator` used to define the discriminant of an object, the level of the object; 14.1/3
 - $\{AI95-00416-01\}$ $\{AI05-0024-1\}$ for an `allocator` used to define the constraint in a `subtype_indication` in any other context, the level of the master that elaborates the `subtype_indication`. 14.2/3
 - *This paragraph was deleted.* $\{AI95-00416-01\}$ $\{AI05-0024-1\}$ 14.3/3

$\{AI95-00416-01\}$ $\{AI05-0024-1\}$ $\{AI05-0066-1\}$ In the first case, the allocated object is said to be a *coextension* of the object whose discriminant designates it, as well as of any object of which the discriminated object is itself a coextension or subcomponent. If the allocated object is a coextension of an anonymous object representing the result of an aggregate or function call that is used (in its entirety) to directly initialize a part of an object, after the result is assigned, the coextension becomes a coextension of the object being initialized and is no longer considered a coextension of the anonymous object. All coextensions of an object [(which have not thus been transferred by such an initialization)] are finalized when the object is finalized (see 7.6.1). 14.4/3

Ramification: The rules of access discriminants are such that when the space for an object with a coextension is reclaimed, the space for the coextensions can be reclaimed. Hence, there is implementation advice (see 13.11) that an object and its coextensions all be allocated from the same storage pool (or stack frame, in the case of a declared object). 14.a.1/2
- $\{AI05-0051-1\}$ Within a return statement, the accessibility level of the anonymous access type of an access result is that of the master of the call. 14.5/3

- 15/3 • *{AI05-0014-1}* The accessibility level of a view of an object or subprogram designated by an access value is the same as that of the access type.
- 15.a/3 **Discussion:** *{AI05-0005-1}* *{AI05-0014-1}* This rule applies even when no dereference exists, for example when an access value is passed as an access parameter. This rule ensures that implementations are not required to include dynamic accessibility values with all access values.
- 16 • The accessibility level of a component, protected subprogram, or entry of (a view of) a composite object is the same as that of (the view of) the composite object.
- 16.1/3 *{AI95-00416-01}* *{AI05-0262-1}* In the above rules, the operand of a view conversion, parenthesized expression or `qualified_expression` is considered to be used in a context if the view conversion, parenthesized expression or `qualified_expression` itself is used in that context. Similarly, a `dependent_expression` of a `conditional_expression` is considered to be used in a context if the `conditional_expression` itself is used in that context.
- 17 One accessibility level is defined to be *statically deeper* than another in the following cases:
 - 18 • For a master that is statically nested within another master, the accessibility level of the inner master is statically deeper than that of the outer master.
 - 18.a **To be honest:** Strictly speaking, this should talk about the *constructs* (such as `subprogram_bodies`) being statically nested within one another; the masters are really the *executions* of those constructs.
 - 18.b **To be honest:** If a given accessibility level is statically deeper than another, then each level defined to be the same as the given level is statically deeper than each level defined to be the same as the other level.
 - 18.1/2 • *{AI95-00254-01}* The accessibility level of the anonymous access type of an access parameter specifying an access-to-subprogram type is statically deeper than that of any master; all such anonymous access types have this same level.
 - 18.c/2 **Ramification:** This rule means that it is illegal to convert an access parameter specifying an access to subprogram to a named access to subprogram type, but it is allowed to pass such an access parameter to another access parameter (the implicit conversion's accessibility will succeed).
 - 19/3 • *{AI95-00254-01}* *{AI05-0082-1}* The statically deeper relationship does not apply to the accessibility level of the anonymous type of an access parameter specifying an access-to-object type nor does it apply to a descendant of a generic formal type; that is, such an accessibility level is not considered to be statically deeper, nor statically shallower, than any other.
 - 19.1/3 • *{AI05-0148-1}* The statically deeper relationship does not apply to the accessibility level of the type of a stand-alone object of an anonymous access-to-object type; that is, such an accessibility level is not considered to be statically deeper, nor statically shallower, than any other.
 - 19.a/3 **Ramification:** In these cases, we use dynamic accessibility checks.
 - 19.2/3 • *{AI05-0142-4}* *{AI05-0235-1}* Inside a return statement that applies to a function *F*, when determining whether the accessibility level of an explicitly aliased parameter of *F* is statically deeper than the level of the return object of *F*, the level of the return object is considered to be the same as that of the level of the explicitly aliased parameter; for statically comparing with the level of other entities, an explicitly aliased parameter of *F* is considered to have the accessibility level of the body of *F*.
 - 19.3/3 • *{AI05-0051-1}* *{AI05-0234-1}* *{AI05-0235-1}* For determining whether a level is statically deeper than the level of the anonymous access type of an access result of a function, when within a return statement that applies to the function, the level of the master of the call is presumed to be the same as that of the level of the master that elaborated the function body.
 - 19.b/3 **To be honest:** *{AI05-0235-1}* This rule has no effect if the previous bullet also applies (that is, the “a level” is of an explicitly aliased parameter).
 - 20 • [For determining whether one level is statically deeper than another when within a generic package body, the generic package is presumed to be instantiated at the same level as where it was declared; run-time checks are needed in the case of more deeply nested instantiations.]

- Proof:** {AI05-0082-1} A generic package does not introduce a new master, so it has the static level of its declaration; the rest follows from the other “statically deeper” rules. 20.a/3
- For determining whether one level is statically deeper than another when within the declarative region of a `type_declaration`, the current instance of the type is presumed to be an object created at a deeper level than that of the type. 21
- Ramification:** In other words, the rules are checked at compile time of the `type_declaration`, in an assume-the-worst manner. 21.a
- The accessibility level of all library units is called the *library level*; a library-level declaration or entity is one whose accessibility level is the library level. 22
- Ramification:** `Library_unit_declarations` are library level. Nested declarations are library level if they are nested only within packages (possibly more than one), and not within subprograms, tasks, etc. 22.a
- To be honest:** The definition of the accessibility level of the anonymous type of an access parameter specifying an access-to-object type cheats a bit, since it refers to the view designated by the actual, but access values designate objects, not views of objects. What we really mean is the view that “would be” denoted by an expression “`X.all`”, where X is the actual, even though such an expression is a figment of our imagination. The definition is intended to be equivalent to the following more verbose version: The accessibility level of the anonymous type of an access parameter is as follows: 22.b/2
- if the actual is an expression of a named access type — the accessibility level of that type; 22.c
 - if the actual is an `allocator` — the accessibility level of the execution of the called subprogram; 22.d
 - if the actual is a reference to the `Access` attribute — the accessibility level of the view denoted by the `prefix`; 22.e/1
 - if the actual is a reference to the `Unchecked_Access` attribute — library accessibility level; 22.f
 - if the actual is an access parameter — the accessibility level of its type. 22.g
- Note that the `allocator` case is explicitly mentioned in the RM95, because otherwise the definition would be circular: the level of the anonymous type is that of the view designated by the actual, which is that of the access type. 22.h
- Discussion:** A deeper accessibility level implies a shorter maximum lifetime. Hence, when a rule requires X to have a level that is “not deeper than” Y’s level, this requires that X has a lifetime at least as long as Y. (We say “maximum lifetime” here, because the accessibility level really represents an upper bound on the lifetime; an object created by an `allocator` can have its lifetime prematurely ended by an instance of `Unchecked_Deallocation`.) 22.i
- Package elaborations are not masters, and are therefore invisible to the accessibility rules: an object declared immediately within a package has the same accessibility level as an object declared immediately within the declarative region containing the package. This is true even in the body of a package; it jibes with the fact that objects declared in a `package_body` live as long as objects declared outside the package, even though the body objects are not visible outside the package. 22.j
- Note that the level of the *view* denoted by `X.all` can be different from the level of the *object* denoted by `X.all`. The former is determined by the type of X; the latter is determined either by the type of the `allocator`, or by the master in which the object was declared. The former is used in several Legality Rules and run-time checks; the latter is used to define when `X.all` gets finalized. The level of a view reflects what we can conservatively “know” about the object of that view; for example, due to `type_conversions`, an access value might designate an object that was allocated by an `allocator` for a different access type. 22.k
- Similarly, the level of the view denoted by `X.all.Comp` can be different from the level of the object denoted by `X.all.Comp`. 22.l
- If Y is statically deeper than X, this implies that Y will be (dynamically) deeper than X in all possible executions. 22.m
- Most accessibility checking is done at compile time; the rules are stated in terms of “statically deeper than”. The exceptions are: 22.n
- Checks involving access parameters of an access-to-object type. The fact that “statically deeper than” is not defined for the anonymous access type of an access parameter implies that any rule saying “shall not be statically deeper than” does not apply to such a type, nor to anything defined to have “the same” level as such a type. 22.o/2
 - {AI05-0082-1} Checks involving generic formal types and their descendants. This is because the actual type can be more or less deeply nested than the generic unit. Note that this only applies to the generic unit itself, and not to the instance. Any static checks needed in the instance will be performed. Any other checks (such as those in the generic body) will require a run-time check of some sort (although implementations that macro-expand generics can determine the result of the check when the generic is expanded). 22.o.1/3
 - {AI05-0082-1} Checks involving other entities and views within generic packages. This is because an instantiation can be at a level that is more deeply nested than the generic package itself. In implementations 22.p/3

- that use a macro-expansion model of generics, these violations can be detected at macro-expansion time. For implementations that share generics, run-time code is needed to detect the error.
- 22.q/2 • *{AI95-00318-02}* *{AI95-00344-01}* *{AI95-00416-01}* Checks during function return and allocators, for nested type extensions and access discriminants.
- 22.r/3 *{AI05-0005-1}* Note that run-time checks are not required for access discriminants (except during function returns and allocators), because their accessibility is determined statically by the accessibility level of the enclosing object.
- 22.s/2 The accessibility level of the result object of a function reflects the time when that object will be finalized; we don't allow pointers to the object to survive beyond that time.
- 22.t We sometimes use the terms “accessible” and “inaccessible” to mean that something has an accessibility level that is not deeper, or deeper, respectively, than something else.
- 22.u/2 **Implementation Note:** *{AI95-00318-02}* *{AI95-00344-01}* *{AI95-00416-01}* If an accessibility Legality Rule is satisfied, then the corresponding run-time check (if any) cannot fail (and a reasonable implementation will not generate any checking code) unless one of the cases requiring run-time checks mentioned previously is involved.
- 22.v Accessibility levels are defined in terms of the relations “the same as” and “deeper than”. To make the discussion more concrete, we can assign actual numbers to each level. Here, we assume that library-level accessibility is level 0, and each level defined as “deeper than” is one level deeper. Thus, a subprogram directly called from the environment task (such as the main subprogram) would be at level 1, and so on.
- 22.w/2 Accessibility is not enforced at compile time for access parameters of an access-to-object type. The “obvious” implementation of the run-time checks would be inefficient, and would involve distributed overhead; therefore, an efficient method is given below. The “obvious” implementation would be to pass the level of the caller at each subprogram call, task creation, etc. This level would be incremented by 1 for each dynamically nested master. An `Accessibility_Check` would be implemented as a simple comparison — checking that X is not deeper than Y would involve checking that $X \leq Y$.
- 22.x A more efficient method is based on passing *static* nesting levels (within constructs that correspond at run time to masters — packages don't count). Whenever an access parameter is passed, an implicit extra parameter is passed with it. The extra parameter represents (in an indirect way) the accessibility level of the anonymous access type, and, therefore, the level of the view denoted by a dereference of the access parameter. This is analogous to the implicit “Constrained” bit associated with certain formal parameters of an unconstrained but definite composite subtype. In this method, we avoid distributed overhead: it is not necessary to pass any extra information to subprograms that have no access parameters. For anything other than an access parameter and its anonymous type, the static nesting level is known at compile time, and is defined analogously to the RM95 definition of accessibility level (e.g. derived access types get their nesting level from their parent). Checking “not deeper than” is a “ \leq ” test on the levels.
- 22.y/2 For each access parameter of an access-to-object type, the static depth passed depends on the actual, as follows:
- 22.z • If the actual is an expression of a named access type, pass the static nesting level of that type.
- 22.aa • If the actual is an allocator, pass the static nesting level of the caller, plus one.
- 22.bb/1 • If the actual is a reference to the `Access` attribute, pass the level of the view denoted by the prefix.
- 22.cc • If the actual is a reference to the `Unchecked_Access` attribute, pass 0 (the library accessibility level).
- 22.dd/2 • If the actual is an access parameter of an access-to-object type, usually just pass along the level passed in. However, if the static nesting level of the formal (access) parameter is greater than the static nesting level of the actual (access) parameter, the level to be passed is the minimum of the static nesting level of the access parameter and the actual level passed in.
- 22.ee/2 For the `Accessibility_Check` associated with a `type_conversion` of an access parameter of an access-to-object type of a given subprogram to a named access type, if the target type is statically nested within the subprogram, do nothing; the check can't fail in this case. Otherwise, check that the value passed in is \leq the static nesting depth of the target type. The other `Accessibility_Checks` are handled in a similar manner.
- 22.ff This method, using statically known values most of the time, is efficient, and, more importantly, avoids distributed overhead.
- 22.ff.1/3 *{AI05-0148-1}* The implementation of accessibility checks for stand-alone objects of anonymous access-to-object types can be similar to that for anonymous access-to-object parameters. A static level suffices; it can be calculated using rules similar to those previously described for access parameters.
- 22.ff.2/3 *{AI05-0148-1}* One important difference between the stand-alone access variables and access parameters is that one can assign a local access parameter to a more global stand-alone access variable. Similarly, one can assign a more global access parameter to a more local stand-alone access variable.
- 22.ff.3/3 *{AI05-0148-1}* For these cases, it is important to note that the “correct” static accessibility level for an access parameter assigned to a stand-alone access object is the minimum of the passed in level and the static accessibility level of the stand-alone object itself. This is true since the static accessibility level passed in might be deeper than that

of the stand-alone object, but the dynamic accessibility of the passed in object clearly must be shallower than the stand-alone object (whatever is passed in must live at least as long as the subprogram call). We do not need to keep a more local static level as accesses to objects statically deeper than the stand-alone object cannot be stored into the stand-alone object.

Discussion: Examples of accessibility:

```

{AI05-0005-1} package body Lib_Unit is
  type T is tagged ...;
  type A0 is access all T;
  Global: A0 := ...;
  procedure P(X: in out T) is
    Y: aliased T;
    type A1 is access all T;
    Ptr0: A0 := Global; -- OK.
    Ptr1: A1 := X'Access; -- OK.
  begin
    Ptr1 := Y'Access; -- OK;
    Ptr0 := A0(Ptr1); -- Illegal type conversion!
    Ptr0 := X'Access; -- Illegal reference to Access attribute!
    Ptr0 := Y'Access; -- Illegal reference to Access attribute!
    Global := Ptr0; -- OK.
  end P;
end Lib_Unit;

```

22.gg
22.hh/3

{AI05-0005-1} The above illegal statements are illegal because the accessibility levels of X and Y are statically deeper than the accessibility level of A0. In every possible execution of any program including this library unit, if P is called, the accessibility level of X will be (dynamically) deeper than that of A0. Note that the accessibility levels of X and Y are the same.

22.ii/3

Here's an example involving access parameters of an access-to-object type:

22.jj/2

```

procedure Main is
  type Level_1_Type is access all Integer;
  procedure P(X: access Integer) is
    type Nested_Type is access all Integer;
  begin
    ... Nested_Type(X) ... -- (1)
    ... Level_1_Type(X) ... -- (2)
  end P;
  procedure Q(X: access Integer) is
    procedure Nested(X: access Integer) is
      begin
        P(X);
      end Nested;
    begin
      Nested(X);
    end Q;
  procedure R is
    Level_2: aliased Integer;
  begin
    Q(Level_2'Access); -- (3)
  end R;
  Level_1: aliased Integer;
begin
  Q(Level_1'Access); -- (4)
  R;
end Main;

```

22.kk

22.ll

22.mm

22.nn

22.oo

The run-time `Accessibility_Check` at (1) can never fail, and no code should be generated to check it. The check at (2) will fail when called from (3), but not when called from (4).

22.pp

Within a `type_declaration`, the rules are checked in an assume-the-worst manner. For example:

22.qq

```

22.r/3      {AI05-0298-1} package P is
            type Int_Ptr is access all Integer;
            type Rec(D: access Integer) is limited private;
private
            type Rec_Ptr is access all Rec;
            function F(X: Rec_Ptr) return Boolean;
            function G(X: access Rec) return Boolean;
            type Rec(D: access Integer) is
              limited record
                C1: Int_Ptr := Int_Ptr(D); -- Illegal!
                C2: Rec_Ptr := Rec'Access; -- Illegal!
                C3: Boolean := F(Rec'Access); -- Illegal!
                C4: Boolean := G(Rec'Access);
              end record;
            end P;

```

22.ss C1, C2, and C3 are all illegal, because one might declare an object of type Rec at a more deeply nested place than the declaration of the type. C4 is legal, but the accessibility level of the object will be passed to function G, and constraint checks within G will prevent it from doing any evil deeds.

22.tt Note that we cannot defer the checks on C1, C2, and C3 until compile-time of the object creation, because that would cause violation of the privacy of private parts. Furthermore, the problems might occur within a task or protected body, which the compiler can't see while compiling an object creation.

23 The following attribute is defined for a prefix X that denotes an aliased view of an object:

24/1 X'Access {8652/0010} {AI95-00127-01} X'Access yields an access value that designates the object denoted by X. The type of X'Access is an access-to-object type, as determined by the expected type. The expected type shall be a general access type. X shall denote an aliased view of an object[, including possibly the current instance (see 8.6) of a limited type within its definition, or a formal parameter or generic formal object of a tagged type]. The view denoted by the prefix X shall satisfy the following additional requirements, presuming the expected type for X'Access is the general access type A with designated type D:

- 25 • If A is an access-to-variable type, then the view shall be a variable; [on the other hand, if A is an access-to-constant type, the view may be either a constant or a variable.]

25.a **Discussion:** The current instance of a limited type is considered a variable.

- 26/3 • {AI95-00363-01} {AI05-0008-1} {AI05-0041-1} The view shall not be a subcomponent that depends on discriminants of an object unless the object is known to be constrained.

26.a **Discussion:** This restriction is intended to be similar to the restriction on renaming discriminant-dependent subcomponents.

26.b **Reason:** This prevents references to subcomponents that might disappear or move or change constraints after creating the reference.

26.c **Implementation Note:** There was some thought to making this restriction more stringent, roughly: "X shall not denote a subcomponent of a variable with discriminant-dependent subcomponents, if the nominal subtype of the variable is an unconstrained definite subtype." This was because in some implementations, it is not just the discriminant-dependent subcomponents that might move as the result of an assignment that changed the discriminants of the enclosing object. However, it was decided not to make this change because a reasonable implementation strategy was identified to avoid such problems, as follows:

- 26.d • Place non-discriminant-dependent components with any aliased parts at offsets preceding any discriminant-dependent components in a discriminated record type with defaulted discriminants.
- 26.e • Preallocate the maximum space for unconstrained discriminated variables with aliased subcomponents, rather than allocating the initial size and moving them to a larger (heap-resident) place if they grow as the result of an assignment.

26.f Note that for objects of a by-reference type, it is not an error for a programmer to take advantage of the fact that such objects are passed by reference. Therefore, the above approach is also necessary for discriminated record types with components of a by-reference type.

26.g To make the above strategy work, it is important that a component of a derived type is defined to be discriminant-dependent if it is inherited and the parent subtype constraint is defined in terms of a discriminant of the derived type (see 3.7).

- {8652/0010} {AI95-00127-01} {AI95-00363-01} If *A* is a named access type and *D* is a tagged type, then the type of the view shall be covered by *D*; if *A* is anonymous and *D* is tagged, then the type of the view shall be either *D*'Class or a type covered by *D*; if *D* is untagged, then the type of the view shall be *D*, and either: 27/2
 - {AI95-00363-01} the designated subtype of *A* shall statically match the nominal subtype of the view; or 27.1/2
 - {AI95-00363-01} {AI05-0041-1} *D* shall be discriminated in its full view and unconstrained in any partial view, and the designated subtype of *A* shall be unconstrained. For the purposes of determining within a generic body whether *D* is unconstrained in any partial view, a discriminated subtype is considered to have a constrained partial view if it is a descendant of an untagged generic formal private or derived type. 27.2/3
- Implementation Note:** This ensures that the dope for an aliased array object can always be stored contiguous with it, but need not be if its nominal subtype is constrained. 27.a
- Ramification:** {8652/0010} {AI95-00127-01} An access attribute can be used as the controlling operand in a dispatching call; see 3.9.2. 27.a.1/1
- {AI95-00363-01} This does not require that types have a partial view in order to allow an access attribute of an unconstrained discriminated object, only that any partial view that does exist is unconstrained. 27.a.2/2
- {AI05-0041-1} The accessibility level of the view shall not be statically deeper than that of the access type *A*. 28/3
- Ramification:** In an instance body, a run-time check applies. 28.a
- {AI95-00230-01} If *A* is an anonymous access-to-object type of an access parameter, then the view can never have a deeper accessibility level than *A*. The same is true for an anonymous access-to-object type of an access discriminant, except when *X*'Access is used to initialize an access discriminant of an object created by an allocator. The latter case is illegal if the accessibility level of *X* is statically deeper than that of the access type of the allocator; a run-time check is needed in the case where the initial value comes from an access parameter. Other anonymous access-to-object types have "normal" accessibility checks. 28.b/2
- {AI05-0041-1} In addition to the places where Legality Rules normally apply (see 12.3), these requirements apply also in the private part of an instance of a generic unit. 28.1/3
- A check is made that the accessibility level of *X* is not deeper than that of the access type *A*. If this check fails, `Program_Error` is raised. 29
- Ramification:** The check is needed for access parameters of an access-to-object type and in instance bodies. 29.a/2
- {AI05-0024-1} Because there are no access parameters permitted for task entries, the accessibility levels are always comparable. We would have to switch to the terminology used in 4.8 and 6.5 based on inclusion within masters if we relax this restriction. That might introduce unacceptable distributed overhead. 29.a.1/3
- Implementation Note:** {AI05-0148-1} This check requires that some indication of lifetime is passed as an implicit parameter along with access parameters of an access-to-object type. A similar indication is required for stand-alone objects of anonymous access-to-object types. No such requirement applies to other anonymous access types, since the checks associated with them are all compile-time checks. 29.b/3
- If the nominal subtype of *X* does not statically match the designated subtype of *A*, a view conversion of *X* to the designated subtype is evaluated (which might raise `Constraint_Error` — see 4.6) and the value of *X*'Access designates that view. 30
- The following attribute is defined for a prefix *P* that denotes a subprogram: 31
- P*'Access {AI95-00229-01} {AI95-00254-01} {AI05-0239-1} *P*'Access yields an access value that designates the subprogram denoted by *P*. The type of *P*'Access is an access-to-subprogram type (*S*), as determined by the expected type. The accessibility level of *P* shall not be statically deeper than that of *S*. In addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit. The profile of *P* shall be subtype conformant with the designated profile of *S*, and shall not be Intrinsic. If the subprogram denoted by *P* is declared within a generic unit, and the expression *P*'Access 32/3

occurs within the body of that generic unit or within the body of a generic unit declared within the declarative region of the generic unit, then the ultimate ancestor of *S* shall be either a nonformal type declared within the generic unit or an anonymous access type of an access parameter.

- 32.a/2 **Discussion:** {AI95-00229-01} The part about generic bodies is worded in terms of the denoted subprogram, not the denoted view; this implies that renaming is invisible to this part of the rule. “Declared within the declarative region of the generic” is referring to child and nested generic units. This rule is partly to prevent contract model problems with respect to the accessibility rules, and partly to ease shared-generic-body implementations, in which a subprogram declared in an instance needs to have a different calling convention from other subprograms with the same profile.
- 32.b Overload resolution ensures only that the profile is type conformant. This rule specifies that subtype conformance is required (which also requires matching calling conventions). *P* cannot denote an entry because access-to-subprogram types never have the *entry* calling convention. *P* cannot denote an enumeration literal or an attribute function because these have intrinsic calling conventions.

Legality Rules

- 32.1/3 {AI05-0188-1} An expression is said to have *distributed accessibility* if it is
- 32.2/3 • a `conditional_expression` (see 4.5.7); or
- 32.3/3 • a view conversion, `qualified_expression`, or parenthesized expression whose operand has distributed accessibility.
- 32.4/3 {AI05-0188-1} The statically deeper relationship does not apply to the accessibility level of an expression having distributed accessibility; that is, such an accessibility level is not considered to be statically deeper, nor statically shallower, than any other.
- 32.5/3 {AI05-0188-1} Any static accessibility requirement that is imposed on an expression that has distributed accessibility (or on its type) is instead imposed on the *dependent_expressions* of the underlying `conditional_expression`. This rule is applied recursively if a *dependent_expression* also has distributed accessibility.
- 32.c/3 **Discussion:** This means that any Legality Rule requiring that the accessibility level of an expression (or that of the type of an expression) shall or shall not be statically deeper than some other level also applies, in the case where the expression has distributed accessibility, to each *dependent_expression* of the underlying `conditional_expression`.

NOTES

- 33 88 The `Unchecked_Access` attribute yields the same result as the `Access` attribute for objects, but has fewer restrictions (see 13.10). There are other predefined operations that yield access values: an `allocator` can be used to create an object, and return an access value that designates it (see 4.8); evaluating the literal `null` yields a null access value that designates no entity at all (see 4.2).
- 34/2 89 {AI95-00230-01} The predefined operations of an access type also include the assignment operation, qualification, and membership tests. Explicit conversion is allowed between general access types with matching designated subtypes; explicit conversion is allowed between access-to-subprogram types with subtype conformant profiles (see 4.6). Named access types have predefined equality operators; anonymous access types do not, but they can use the predefined equality operators for *universal_access* (see 4.5.2).
- 34.a/2 **Reason:** {AI95-00230-01} Anonymous access types can use the universal access equality operators declared in Standard, while named access types cannot for compatibility reasons. By not having equality operators for anonymous access types, we eliminate the need to specify exactly where the predefined operators for anonymous access types would be defined, as well as the need for an implementer to insert an implicit declaration for "=", etc. at the appropriate place in their symbol table. Note that ":", "Access", and ".all" are defined.
- 35 90 The object or subprogram designated by an access value can be named with a dereference, either an `explicit_dereference` or an `implicit_dereference`. See 4.1.
- 36 91 A call through the dereference of an access-to-subprogram value is never a dispatching call.
- 36.a **Proof:** See 3.9.2.
- 37/2 92 {AI95-00254-01} The `Access` attribute for subprograms and parameters of an anonymous access-to-subprogram type may together be used to implement “downward closures” — that is, to pass a more-nested subprogram as a parameter to a less-nested subprogram, as might be appropriate for an iterator abstraction or numerical integration. Downward closures can also be implemented using generic formal subprograms (see 12.6). Note that `Unchecked_Access` is not allowed for subprograms.

- 93 Note that using an access-to-class-wide tagged type with a dispatching operation is a potentially more structured alternative to using an access-to-subprogram type. 38
- 94 An implementation may consider two access-to-subprogram values to be unequal, even though they designate the same subprogram. This might be because one points directly to the subprogram, while the other points to a special prologue that performs an `Elaboration_Check` and then jumps to the subprogram. See 4.5.2. 39
- Ramification:** If equality of access-to-subprogram values is important to the logic of a program, a reference to the `Access` attribute of a subprogram should be evaluated only once and stored in a global constant for subsequent use and equality comparison. 39.a

*Examples**Example of use of the Access attribute:*

```
Martha : Person_Name := new Person(F);      -- see 3.10.1
Cars   : array (1..2) of aliased Car;      41
...
Martha.Vehicle := Cars(1) 'Access;
George.Vehicle := Cars(2) 'Access;
```

Extensions to Ada 83

We no longer make things like `'Last` and `".component"` (basic) operations of an access type that need to be "declared" somewhere. Instead, implicit dereference in a prefix takes care of them all. This means that there should never be a case when `X.all'Last` is legal while `X'Last` is not. See AI83-00154. 41.a

Incompatibilities With Ada 95

{AI95-00363-01} Aliased variables are not necessarily constrained in Ada 2005 (see 3.6). Therefore, a subcomponent of an aliased variable may disappear or change shape, and taking `'Access` of such a subcomponent thus is illegal, while the same operation would have been legal in Ada 95. Note that most allocated objects are still constrained by their initial value (see 4.8), and thus legality of `'Access` didn't change for them. For example: 41.b/2

```
type T1 (D1 : Boolean := False) is      41.c/2
  record
    case D1 is
      when False =>
        C1 : aliased Integer;
      when True =>
        null;
    end case;
  end record;
type Acc_Int is access all Integer;

A_T : aliased T1;                      41.d/2
Ptr  : Acc_Int := A_T.C1 'Access; -- Illegal in Ada 2005, legal in Ada 95
A_T := (D1 => True); -- Raised Constraint_Error in Ada 95, but does not
                    -- in Ada 2005, so Ptr would become invalid when this
                    -- is assigned (thus Ptr is illegal).
```

{AI95-00363-01} If a discriminated full type has a partial view (private type) that is constrained, we do not allow `'Access` on objects to create a value of an object of an access-to-unconstrained type. Ada 95 allowed this attribute and various access subtypes, requiring that the heap object be constrained and thus making details of the implementation of the private type visible to the client of the private type. See 4.8 for more on this topic. 41.e/2

{AI95-00229-01} {AI95-00254-01} **Amendment Correction:** Taking `'Access` of a subprogram declared in a generic unit in the body of that generic is no longer allowed. Such references can easily be used to create dangling pointers, as Legality Rules are not rechecked in instance bodies. At the same time, the rules were loosened a bit where that is harmless, and also to allow any routine to be passed to an access parameter of an access-to-subprogram type. The now illegal uses of `'Access` can almost always be moved to the private part of the generic unit, where they are still legal (and rechecked upon instantiation for possibly dangling pointers). 41.f/2

Extensions to Ada 95

{8652/0010} {AI95-00127-01} **Corrigendum:** Access attributes of objects of class-wide types can be used as the controlling parameter in a dispatching calls (see 3.9.2). This was an oversight in Ada 95. 41.g/2

{AI95-00235-01} **Amendment Correction:** The type of the prefix can now be used in resolving `Access` attributes. This allows more uses of the `Access` attribute to resolve. For example: 41.h/2

```
type Int_Ptr is access all Integer;      41.i/2
type Float_Ptr is access all Float;
```

- 41.j/2 `function Zap (Val : Int_Ptr) return Float;`
 `function Zap (Val : Float_Ptr) return Float;`
- 41.k/2 `Value : aliased Integer := 10;`
- 41.l/2 `Result1 : Float := Zap (Value'access); -- Ambiguous in Ada 95; resolves in Ada 2005.`
 `Result2 : Float := Zap (Int_Ptr'(Value'access)); -- Resolves in Ada 95 and Ada 2005.`
- 41.m/2 This change is upward compatible; any expression that does not resolve by the new rules would have failed a Legality Rule.

Wording Changes from Ada 95

- 41.n/2 {AI95-00162-01} Adjusted the wording to reflect the fact that expressions and function calls are masters.
- 41.o/2 {AI95-00230-01} {AI95-00254-01} {AI95-00318-02} {AI95-00385-01} {AI95-00416-01} Defined the accessibility of the various new kinds and uses of anonymous access types.

Incompatibilities With Ada 2005

- 41.p/3 {AI05-0008-1} **Correction:** Simplified the description of when a discriminant-dependent component is allowed as the prefix of 'Access to when the object is known to be constrained. This fixes a confusion as to whether a subcomponent of an object that is not certain to be constrained can be used as a prefix of 'Access. The fix introduces an incompatibility, as the rule did not apply in Ada 95 if the prefix was a constant; but it now applies no matter what kind of object is involved. The incompatibility is not too bad, since most kinds of constants are known to be constrained.
- 41.q/3 {AI05-0041-1} **Correction:** Corrected the checks for the constrainedness of the prefix of the Access attribute so that assume-the-worst is used in generic bodies. This may make some programs illegal, but those programs were at risk having objects disappear while valid access values still pointed at them.

Extensions to Ada 2005

- 41.r/3 {AI05-0082-1} **Correction:** Eliminated the static accessibility definition for generic formal types, as the actual can be more or less nested than the generic itself. This allows programs that were illegal for Ada 95 and for Ada 2005.
- 41.s/3 {AI05-0148-1} {AI05-0253-1} Eliminate the static accessibility definition for stand-alone objects of anonymous access-to-object types. This allows such objects to be used as temporaries without causing accessibility problems.

Wording Changes from Ada 2005

- 41.t/3 {AI05-0014-1} **Correction:** Corrected the rules so that the accessibility of the object designated by an access object is that of the access type, even when no dereference is given. The accessibility was not specified in the past. This correction applies to both Ada 95 and Ada 2005.
- 41.u/3 {AI05-0024-1} **Correction:** Corrected accessibility rules for access discriminants so that no cases are omitted.
- 41.v/3 {AI05-0051-1} {AI05-0234-1} {AI05-0235-1} {AI05-0284-1} **Correction:** Corrected accessibility rules for anonymous access return types and access discriminants in return statements.
- 41.w/3 {AI05-0066-1} **Correction:** Changed coextension rules so that coextensions that belong to an anonymous object are transferred to the ultimate object.
- 41.x/3 {AI05-0142-4} {AI05-0188-1} {AI05-0235-1} Defined the accessibility of explicitly aliased parameters (see 6.1) and conditional_expressions (see 4.5.7).
- 41.y/3 {AI05-0234-1} **Correction:** Defined the term “master of the call” to simplify other wording, especially that for the accessibility checks associated with return statements and explicitly aliased parameters.
- 41.z/3 {AI05-0270-1} **Correction:** Defined the (omitted) accessibility level of null values when those are passed as the actual of an access-to-object parameter.

3.11 Declarative Parts

- 1 [A declarative_part contains declarative_items (possibly none).]

Syntax

- 2 declarative_part ::= {declarative_item}
- 3 declarative_item ::=
 basic_declarative_item | body

`{8652/0009} {AI95-00137-01} basic_declarative_item ::=` 4/1
`basic_declaration | aspect_clause | use_clause`

`body ::= proper_body | body_stub` 5

`proper_body ::=` 6
`subprogram_body | package_body | task_body | protected_body`

Static Semantics

`{AI95-00420-01}` The list of `declarative_items` of a `declarative_part` is called the *declaration list* of the `declarative_part`. 6.1/2

Dynamic Semantics

The elaboration of a `declarative_part` consists of the elaboration of the `declarative_items`, if any, in the order in which they are given in the `declarative_part`. 7

An elaborable construct is in the *elaborated* state after the normal completion of its elaboration. Prior to that, it is *not yet elaborated*. 8

Ramification: The elaborated state is only important for bodies; certain uses of a body raise an exception if the body is not yet elaborated. 8.a

Note that "prior" implies before the start of elaboration, as well as during elaboration. 8.b

The use of the term "normal completion" implies that if the elaboration propagates an exception or is aborted, the declaration is not elaborated. RM83 missed the aborted case. 8.c

For a construct that attempts to use a body, a check (`Elaboration_Check`) is performed, as follows: 9

- `{8652/0014} {AI95-00064-01}` For a call to a (non-protected) subprogram that has an explicit body, a check is made that the body is already elaborated. This check and the evaluations of any actual parameters of the call are done in an arbitrary order. 10/1

Discussion: AI83-00180 specifies that there is no elaboration check for a subprogram defined by a `pragma Interface` (or equivalently, `pragma Import`). AI83-00430 specifies that there is no elaboration check for an enumeration literal. AI83-00406 specifies that the evaluation of parameters and the elaboration check occur in an arbitrary order. AI83-00406 applies to generic instantiation as well (see below). 10.a

`{8652/0014} {AI95-00064-01} {AI05-0177-1}` A subprogram can be completed by a `renaming-as-body`, a `null_procedure_declaration`, or an `expression_function_declaration`, and we need to make an elaboration check on such a body, so we use "body" rather than `subprogram_body` above. 10.a.1/3

- `{AI05-0229-1}` For a call to a protected operation of a protected type (that has a body — no check is performed if the protected type is imported — see B.1), a check is made that the `protected_body` is already elaborated. This check and the evaluations of any actual parameters of the call are done in an arbitrary order. 11/3

Discussion: A protected type has only one elaboration "bit," rather than one for each operation, because one call may result in evaluating the barriers of other entries, and because there are no elaborable declarations between the bodies of the operations. In fact, the elaboration of a `protected_body` does not elaborate the enclosed bodies, since they are not considered independently elaborable. 11.a

Note that there is no elaboration check when calling a task entry. Task entry calls are permitted even before the associated `task_body` has been seen. Such calls are simply queued until the task is activated and reaches a corresponding `accept_statement`. We considered a similar rule for protected entries — simply queuing all calls until the `protected_body` was seen, but felt it was not worth the possible implementation overhead, particularly given that there might be multiple instances of the protected type. 11.b

- For the activation of a task, a check is made by the activator that the `task_body` is already elaborated. If two or more tasks are being activated together (see 9.2), as the result of the elaboration of a `declarative_part` or the initialization for the object created by an allocator, this check is done for all of them before activating any of them. 12

Reason: As specified by AI83-00149, the check is done by the activator, rather than by the task itself. If it were done by the task itself, it would be turned into a `Tasking_Error` in the activator, and the other tasks would still be activated. 12.a

- 13 • For the instantiation of a generic unit that has a body, a check is made that this body is already elaborated. This check and the evaluation of any `explicit_generic_actual_parameters` of the instantiation are done in an arbitrary order.

14 The exception `Program_Error` is raised if any of these checks fails.

Extensions to Ada 83

- 14.a/2 {AI95-00114-01} The syntax for `declarative_part` is modified to remove the ordering restrictions of Ada 83; that is, the distinction between `basic_declarative_items` and `later_declarative_items` within `declarative_parts` is removed. This means that things like `use_clauses` and `object_declarations` can be freely intermixed with things like bodies.
- 14.b The syntax rule for `proper_body` now allows a `protected_body`, and the rules for elaboration checks now cover calls on protected operations.

Wording Changes from Ada 83

- 14.c The syntax rule for `later_declarative_item` is removed; the syntax rule for `declarative_item` is new.
- 14.d RM83 defines “elaborated” and “not yet elaborated” for `declarative_items` here, and for other things in 3.1, “Declarations”. That’s no longer necessary, since these terms are fully defined in 3.1.
- 14.e In RM83, all uses of `declarative_part` are optional (except for the one in `block_statement` with a **declare**) which is sort of strange, since a `declarative_part` can be empty, according to the syntax. That is, `declarative_parts` are sort of “doubly optional”. In Ada 95, these `declarative_parts` are always required (but can still be empty). To simplify description, we go further and say (see 5.6, “Block Statements”) that a `block_statement` without an explicit `declarative_part` is equivalent to one with an empty one.

Wording Changes from Ada 95

- 14.f/2 {8652/0009} {AI95-00137-01} **Corrigendum:** Changed representation clauses to aspect clauses to reflect that they are used for more than just representation.
- 14.g/2 {8652/0014} {AI95-00064-01} **Corrigendum:** Clarified that the elaboration check applies to all kinds of subprogram bodies.
- 14.h/2 {AI95-00420-01} Defined “declaration list” to avoid confusion for various rules. Other kinds of declaration list are defined elsewhere.

3.11.1 Completions of Declarations

- 1/3 {8652/0014} {AI95-00064-01} {AI05-0177-1} Declarations sometimes come in two parts. A declaration that requires a second part is said to *require completion*. The second part is called the *completion* of the declaration (and of the entity declared), and is either another declaration, a body, or a pragma. A *body* is a body, an `entry_body`, a `null_procedure_declaration` or an `expression_function_declaration` that completes another declaration, or a renaming-as-body (see 8.5.4).
- 1.a **Discussion:** Throughout the RM95, there are rules about completions that define the following:
- 1.b • Which declarations require a corresponding completion.
 - 1.c • Which constructs can only serve as the completion of a declaration.
 - 1.d • Where the completion of a declaration is allowed to be.
 - 1.e • What kinds of completions are allowed to correspond to each kind of declaration that allows one.
- 1.f Don’t confuse this compile-time concept with the run-time concept of completion defined in 7.6.1.
- 1.g Note that the declaration of a private type (if limited) can be completed with the declaration of a task type, which is then completed with a body. Thus, a declaration can actually come in *three* parts.
- 1.h/3 {AI95-00217-06} {AI05-0162-1} An incomplete type (whether declared in the limited view of a package or not) may be completed by a private type declaration, so we can in fact have *four* parts.
- 1.i/3 {AI05-0229-1} In Ada 2012, there are no language-defined pragmas that act as completions. Pragma Import (which is obsolescent) has the effect of setting aspect `Import` to `True`; such an aspect makes giving a completion illegal. The wording that allows pragmas as completions was left as it is harmless and appears in many places in this Standard.

Name Resolution Rules

- A construct that can be a completion is interpreted as the completion of a prior declaration only if: 2
- The declaration and the completion occur immediately within the same declarative region; 3
 - The defining name or `defining_program_unit_name` in the completion is the same as in the declaration, or in the case of a `pragma`, the `pragma` applies to the declaration; 4
 - If the declaration is overloadable, then the completion either has a type-conformant profile, or is a `pragma`. 5

Legality Rules

{AI05-0229-1} An implicit declaration shall not have a completion. For any explicit declaration that is specified to *require completion*, there shall be a corresponding explicit completion, unless the declared entity is imported (see B.1). 6/3

To be honest: {AI95-00217-06} The implicit declarations occurring in a limited view do have a completion (the explicit declaration occurring in the full view) but that's a special case, since the implicit declarations are actually built from the explicit ones. So they do not *require* a completion, they have one by *fiat*. 6.a.1/2

Discussion: {AI05-0299-1} The implicit declarations of predefined operators are not allowed to have a completion. Enumeration literals, although they are subprograms, are not allowed to have a corresponding `subprogram_body`. That's because the completion rules are described in terms of constructs (`subprogram_declarations`) and not entities (subprograms). When a completion is required, it has to be explicit; the implicit null `package_body` that Clause 7 talks about cannot serve as the completion of a `package_declaration` if a completion is required. 6.a/3

At most one completion is allowed for a given declaration. Additional requirements on completions appear where each kind of completion is defined. 7

Ramification: A subunit is not a completion; the stub is. 7.a

If the completion of a declaration is also a declaration, then *that* declaration might have a completion, too. For example, a limited private type can be completed with a task type, which can then be completed with a task body. This is not a violation of the “at most one completion” rule. 7.b

A type is *completely defined* at a place that is after its full type definition (if it has one) and after all of its subcomponent types are completely defined. A type shall be completely defined before it is frozen (see 13.14 and 7.3). 8

Reason: Index types are always completely defined — no need to mention them. There is no way for a completely defined type to depend on the value of a (still) deferred constant. 8.a

NOTES

95 {AI05-0229-1} Completions are in principle allowed for any kind of explicit declaration. However, for some kinds of declaration, the only allowed completion is an implementation-defined `pragma`, and implementations are not required to have any such `pragmas`. 9/3

This paragraph was deleted. {AI05-0229-1} 9.a/3

96 There are rules that prevent premature uses of declarations that have a corresponding completion. The `Elaboration_Checks` of 3.11 prevent such uses at run time for subprograms, protected operations, tasks, and generic units. The rules of 13.14, “Freezing Rules” prevent, at compile time, premature uses of other entities such as private types and deferred constants. 10

Wording Changes from Ada 83

This subclause is new. It is intended to cover all kinds of completions of declarations, be they a body for a spec, a full type for an incomplete or private type, a full constant declaration for a deferred constant declaration, or a `pragma Import` for any kind of entity. 10.a

Wording Changes from Ada 95

{8652/0014} {AI95-00064-01} **Corrigendum:** Added a definition of *body*, which is different than `body` or **body**. 10.b/2

Wording Changes from Ada 2005

{AI95-0177-1} Added null procedures and expression functions that are completions to the definition of *body*. 10.c/3

4 Names and Expressions

{AI05-0299-1} [The rules applicable to the different forms of name and expression, and to their evaluation, are given in this clause.] 1/3

4.1 Names

[Names can denote declared entities, whether declared explicitly or implicitly (see 3.1). Names can also denote objects or subprograms designated by access values; the results of `type_conversions` or `function_calls`; subcomponents and slices of objects and values; protected subprograms, single entries, entry families, and entries in families of entries. Finally, names can denote attributes of any of the foregoing.] 1

Syntax

```
{AI05-0003-1} {AI05-0139-2} name ::=
  direct_name      | explicit_dereference
  | indexed_component | slice
  | selected_component | attribute_reference
  | type_conversion  | function_call
  | character_literal | qualified_expression
  | generalized_reference | generalized_indexing
```

2/3

```
direct_name ::= identifier | operator_symbol
```

3

Discussion: {AI95-00114-01} `character_literal` is no longer a `direct_name`. `character_literals` are usable even when the corresponding enumeration type declaration is not visible. See 4.2. 3.a/2

```
prefix ::= name | implicit_dereference
```

4

```
explicit_dereference ::= name.all
```

5

```
implicit_dereference ::= name
```

6

{AI05-0004-1} [Certain forms of name (`indexed_components`, `selected_components`, `slices`, and `attribute_references`) include a `prefix` that is either itself a name that denotes some related entity, or an `implicit_dereference` of an access value that designates some related entity.] 7/3

Name Resolution Rules

The name in a *dereference* (either an `implicit_dereference` or an `explicit_dereference`) is expected to be of any access type. 8

Static Semantics

{AI05-0008-1} If the type of the name in a dereference is some access-to-object type *T*, then the dereference denotes a view of an object, the *nominal subtype* of the view being the designated subtype of *T*. If the designated subtype has unconstrained discriminants, the (actual) subtype of the view is constrained by the values of the discriminants of the designated object, except when there is a partial view of the type of the designated subtype that does not have discriminants, in which case the dereference is not constrained by its discriminant values. 9/3

Ramification: If the value of the name is the result of an access type conversion, the dereference denotes a view created as part of the conversion. The nominal subtype of the view is not necessarily the same as that used to create the designated object. See 4.6. 9.a

To be honest: We sometimes refer to the nominal subtype of a particular kind of name rather than the nominal subtype of the view denoted by the name (presuming the name denotes a view of an object). These two uses of nominal subtype are intended to mean the same thing. 9.b

- 9.c/3 **Reason:** *{AI05-0008-1}* The last sentence was not present in Ada 95; it is necessary in Ada 2005 because general access types can designate unconstrained objects, which was not possible in Ada 95. Thus, the rules that had this effect in Ada 95 (the object being constrained by its initial value) don't work in Ada 2005 and we have to say this explicitly.
- 9.d/3 *{AI05-0008-1}* The “except” part of the last sentence prevents privacy “breaking”, so that if a private type has discriminants only in the full view, they don't interfere with freely interassigning values between objects of the type, even when the objects live in the heap.
- 9.e/3 **Implementation Note:** *{AI05-0008-1}* Since we don't depend on whether the designated object is constrained, it is not necessary to include a constrained bit in every object that could be designated by a general access type.
- 10 If the type of the name in a dereference is some access-to-subprogram type *S*, then the dereference denotes a view of a subprogram, the *profile* of the view being the designated profile of *S*.
- 10.a **Ramification:** This means that the formal parameter names and default expressions to be used in a call whose name or prefix is a dereference are those of the designated profile, which need not be the same as those of the subprogram designated by the access value, since 'Access requires only subtype conformance, not full conformance.

Dynamic Semantics

- 11/2 *{AI95-00415-01}* The evaluation of a name determines the entity denoted by the name. This evaluation has no other effect for a name that is a `direct_name` or a `character_literal`.
- 12 [The evaluation of a name that has a prefix includes the evaluation of the prefix.] The evaluation of a prefix consists of the evaluation of the name or the `implicit_dereference`. The prefix denotes the entity denoted by the name or the `implicit_dereference`.
- 13 The evaluation of a dereference consists of the evaluation of the name and the determination of the object or subprogram that is designated by the value of the name. A check is made that the value of the name is not the null access value. `Constraint_Error` is raised if this check fails. The dereference denotes the object or subprogram designated by the value of the name.

*Examples*14 *Examples of direct names:*

- | | | | |
|----|---------------------|---|-------------|
| 15 | <code>Pi</code> | -- the direct name of a number | (see 3.3.2) |
| | <code>Limit</code> | -- the direct name of a constant | (see 3.3.1) |
| | <code>Count</code> | -- the direct name of a scalar variable | (see 3.3.1) |
| | <code>Board</code> | -- the direct name of an array variable | (see 3.6.1) |
| | <code>Matrix</code> | -- the direct name of a type | (see 3.6) |
| | <code>Random</code> | -- the direct name of a function | (see 6.1) |
| | <code>Error</code> | -- the direct name of an exception | (see 11.1) |

16 *Examples of dereferences:*

- | | | |
|----|-----------------------------|---|
| 17 | <code>Next_Car.all</code> | -- explicit dereference denoting the object designated by |
| | | -- the access variable <code>Next_Car</code> (see 3.10.1) |
| | <code>Next_Car.Owner</code> | -- selected component with implicit dereference; |
| | | -- same as <code>Next_Car.all.Owner</code> |

Extensions to Ada 83

- 17.a Type conversions and function calls are now considered names that denote the result of the operation. In the case of a type conversion used as an actual parameter or that is of a tagged type, the type conversion is considered a variable if the operand is a variable. This simplifies the description of “parameters of the form of a type conversion” as well as better supporting an important OOP paradigm that requires the combination of a conversion from a class-wide type to some specific type followed immediately by component selection. Function calls are considered names so that a type conversion of a function call and the function call itself are treated equivalently in the grammar. A function call is considered the name of a constant, and can be used anywhere such a name is permitted. See 6.5.
- 17.b/1 Type conversions of a tagged type are permitted anywhere their operand is permitted. That is, if the operand is a variable, then the type conversion can appear on the left-hand side of an `assignment_statement`. If the operand is an object, then the type conversion can appear in an object renaming or as a prefix. See 4.6.

Wording Changes from Ada 83

{AI95-00114-01} Everything of the general syntactic form `name(...)` is now syntactically a `name`. In any realistic parser, this would be a necessity since distinguishing among the various `name(...)` constructs inevitably requires name resolution. In cases where the construct yields a value rather than an object, the name denotes a value rather than an object. Names already denote values in Ada 83 with named numbers, components of the result of a function call, etc. This is partly just a wording change, and partly an extension of functionality (see Extensions heading above). 17.c/2

The syntax rule for `direct_name` is new. It is used in places where direct visibility is required. It's kind of like Ada 83's `simple_name`, but `simple_name` applied to both direct visibility and visibility by selection, and furthermore, it didn't work right for `operator_symbols`. The syntax rule for `simple_name` is removed, since its use is covered by a combination of `direct_name` and `selector_name`. The syntactic categories `direct_name` and `selector_name` are similar; it's mainly the visibility rules that distinguish the two. The introduction of `direct_name` requires the insertion of one new explicit textual rule: to forbid `statement_identifiers` from being `operator_symbols`. This is the only case where the explicit rule is needed, because this is the only case where the declaration of the entity is implicit. For example, there is no need to syntactically forbid (say) "X: "Rem";", because it is impossible to declare a type whose name is an `operator_symbol` in the first place. 17.d

The syntax rules for `explicit_dereference` and `implicit_dereference` are new; this makes other rules simpler, since dereferencing an access value has substantially different semantics from `selected_components`. We also use `name` instead of `prefix` in the `explicit_dereference` rule since that seems clearer. Note that these rules rely on the fact that function calls are now names, so we don't need to use `prefix` to allow functions calls in front of `.all`. 17.e

Discussion: Actually, it would be reasonable to allow any `primary` in front of `.all`, since only the value is needed, but that would be a bit radical. 17.f

We no longer use the term *appropriate for a type* since we now describe the semantics of a prefix in terms of implicit dereference. 17.g

Extensions to Ada 2005

{AI05-0003-1} A `qualified_expression` is now a `name` denoting a constant view; this allows them to be used as a prefix and to be renamed as an object. They are often used to remove ambiguity from function calls, and there may be no other way to do that. Interestingly, a `type_conversion` of a `qualified_expression` is already legal in these contexts, so this change mainly reduces clutter by eliminating an otherwise unneeded `type_conversion` from some expressions. 17.h/3

Wording Changes from Ada 2005

{AI05-0008-1} **Correction:** Added a missing rule so that most dereferences are assumed constrained (without determining whether the designated object is). This is just confirming the Ada 95 rules; Ada 2005 failed to ensure that this property was unchanged. 17.i/3

{AI05-0139-2} {AI05-0299-1} Added `generalized_reference` and `generalized_indexing` as types of `name`; these are documented as extensions in the appropriate subclauses. 17.j/3

4.1.1 Indexed Components

[An `indexed_component` denotes either a component of an array or an entry in a family of entries.] 1

Syntax

```
indexed_component ::= prefix(expression {, expression}) 2
```

Name Resolution Rules

The `prefix` of an `indexed_component` with a given number of `expressions` shall resolve to denote an array (after any implicit dereference) with the corresponding number of index positions, or shall resolve to denote an entry family of a task or protected object (in which case there shall be only one `expression`). 3

The expected type for each `expression` is the corresponding index type. 4

Static Semantics

When the `prefix` denotes an array, the `indexed_component` denotes the component of the array with the specified index value(s). The nominal subtype of the `indexed_component` is the component subtype of the array type. 5

- 6 When the `prefix` denotes an entry family, the `indexed_component` denotes the individual entry of the entry family with the specified index value.

Dynamic Semantics

- 7 For the evaluation of an `indexed_component`, the `prefix` and the `expressions` are evaluated in an arbitrary order. The value of each `expression` is converted to the corresponding index type. A check is made that each index value belongs to the corresponding index range of the array or entry family denoted by the `prefix`. `Constraint_Error` is raised if this check fails.

Examples

- 8 *Examples of indexed components:*

```

9   My_Schedule (Sat)      -- a component of a one-dimensional array (see 3.6.1)
   Page (10)              -- a component of a one-dimensional array (see 3.6)
   Board (M, J + 1)      -- a component of a two-dimensional array (see 3.6.1)
   Page (10) (20)        -- a component of a component (see 3.6)
   Request (Medium)      -- an entry in a family of entries (see 9.1)
   Next_Frame (L) (M, N) -- a component of a function call (see 6.1)

```

NOTES

- 10 1 *Notes on the examples:* Distinct notations are used for components of multidimensional arrays (such as `Board`) and arrays of arrays (such as `Page`). The components of an array of arrays are arrays and can therefore be indexed. Thus `Page(10)(20)` denotes the 20th component of `Page(10)`. In the last example `Next_Frame(L)` is a function call returning an access value that designates a two-dimensional array.

4.1.2 Slices

- 1 [A slice denotes a one-dimensional array formed by a sequence of consecutive components of a one-dimensional array. A slice of a variable is a variable; a slice of a constant is a constant;] a slice of a value is a value.

Syntax

2 `slice ::= prefix(discrete_range)`

Name Resolution Rules

- 3 The `prefix` of a `slice` shall resolve to denote a one-dimensional array (after any implicit dereference).
 4 The expected type for the `discrete_range` of a `slice` is the index type of the array type.

Static Semantics

- 5 A `slice` denotes a one-dimensional array formed by the sequence of consecutive components of the array denoted by the `prefix`, corresponding to the range of values of the index given by the `discrete_range`.
 6 The type of the `slice` is that of the `prefix`. Its bounds are those defined by the `discrete_range`.

Dynamic Semantics

- 7 For the evaluation of a `slice`, the `prefix` and the `discrete_range` are evaluated in an arbitrary order. If the `slice` is not a *null slice* (a `slice` where the `discrete_range` is a null range), then a check is made that the bounds of the `discrete_range` belong to the index range of the array denoted by the `prefix`. `Constraint_Error` is raised if this check fails.

NOTES

- 8 2 A `slice` is not permitted as the `prefix` of an `Access attribute_reference`, even if the components or the array as a whole are aliased. See 3.10.2.
 8.a **Proof:** Slices are not aliased, by 3.10, “Access Types”.

- Reason:** This is to ease implementation of general-access-to-array. If slices were aliased, implementations would need to store array dope with the access values, which is not always desirable given access-to-incomplete types completed in a package body. 8.b
- 3 For a one-dimensional array A, the slice A(N .. N) denotes an array that has only one component; its type is the type of A. On the other hand, A(N) denotes a component of the array A and has the corresponding component type. 9

*Examples**Examples of slices:*

```

Stars(1 .. 15)           -- a slice of 15 characters      (see 3.6.3)      10
Page(10 .. 10 + Size)  -- a slice of 1 + Size components (see 3.6)      11
Page(L) (A .. B)       -- a slice of the array Page(L) (see 3.6)
Stars(1 .. 0)          -- a null slice                  (see 3.6.3)
My_Schedule(Weekday)  -- bounds given by subtype (see 3.6.1 and 3.5.1)
Stars(5 .. 15) (K)     -- same as Stars(K)              (see 3.6.3)
                       -- provided that K is in 5 .. 15

```

4.1.3 Selected Components

[Selected_components are used to denote components (including discriminants), entries, entry families, and protected subprograms; they are also used as expanded names as described below.] 1

Syntax

```

selected_component ::= prefix . selector_name          2
selector_name ::= identifier | character_literal | operator_symbol 3

```

Name Resolution Rules

A selected_component is called an *expanded name* if, according to the visibility rules, at least one possible interpretation of its prefix denotes a package or an enclosing named construct (directly, not through a subprogram_renaming_declaration or generic_renaming_declaration). 4

Discussion: See AI83-00187. 4.a

A selected_component that is not an expanded name shall resolve to denote one of the following: 5

Ramification: If the prefix of a selected_component denotes an enclosing named construct, then the selected_component is interpreted only as an expanded name, even if the named construct is a function that could be called without parameters. 5.a

- A component [(including a discriminant)]: 6

The prefix shall resolve to denote an object or value of some non-array composite type (after any implicit dereference). The selector_name shall resolve to denote a discriminant_specification of the type, or, unless the type is a protected type, a component_declaration of the type. The selected_component denotes the corresponding component of the object or value. 7

Reason: {A105-0005-1} The components of a protected object cannot be named except by an expanded name, even from within the corresponding protected body. The protected body cannot reference the private components of some arbitrary object of the protected type; the protected body may reference components of the current instance only (by an expanded name or a direct_name). 7.a/3

Ramification: Only the discriminants and components visible at the place of the selected_component can be selected, since a selector_name can only denote declarations that are visible (see 8.3). 7.b

- A single entry, an entry family, or a protected subprogram: 8

The prefix shall resolve to denote an object or value of some task or protected type (after any implicit dereference). The selector_name shall resolve to denote an entry_declaration or subprogram_declaration occurring (implicitly or explicitly) within the visible part of that type. The selected_component denotes the corresponding entry, entry family, or protected subprogram. 9

- 9.a **Reason:** This explicitly says “visible part” because even though the body has visibility on the private part, it cannot call the private operations of some arbitrary object of the task or protected type, only those of the current instance (and expanded name notation has to be used for that).
- 9.1/2 • *{AI95-00252-01}* *{AI95-00407-01}* A view of a subprogram whose first formal parameter is of a tagged type or is an access parameter whose designated type is tagged:
- 9.2/3 *{AI95-00252-01}* *{AI95-00407-01}* *{AI05-0090-1}* The **prefix** (after any implicit dereference) shall resolve to denote an object or value of a specific tagged type *T* or class-wide type *T*Class. The **selector_name** shall resolve to denote a view of a subprogram declared immediately within the declarative region in which an ancestor of the type *T* is declared. The first formal parameter of the subprogram shall be of type *T*, or a class-wide type that covers *T*, or an access parameter designating one of these types. The designator of the subprogram shall not be the same as that of a component of the tagged type visible at the point of the **selected_component**. The subprogram shall not be an implicitly declared primitive operation of type *T* that overrides an inherited subprogram implemented by an entry or protected subprogram visible at the point of the **selected_component**. The **selected_component** denotes a view of this subprogram that omits the first formal parameter. This view is called a *prefixed view* of the subprogram, and the **prefix** of the **selected_component** (after any implicit dereference) is called the *prefix* of the prefixed view.
- 9.b/3 **Discussion:** *{AI05-0090-1}* The part of the rule that excludes a primitive overriding subprogram as a selector applies only to the wrapper subprogram that is implicitly declared to override a subprogram inherited from a synchronized interface that is implemented by an operation of a task or protected type (see 9.1 and 9.4). We don't want calls that use a prefixed view to be ambiguous between the wrapper subprogram and the implementing entry or protected operation. Note that it is illegal to declare an explicit primitive that has a prefixed view that is homographic with one of the type's operations, so in normal cases it isn't possible to have an ambiguity in a prefix call. However, a class-wide operation of an ancestor type that is declared in the same declaration list with the ancestor type is also considered, and that can still make a call ambiguous.
- 10 An expanded name shall resolve to denote a declaration that occurs immediately within a named declarative region, as follows:
- 11 • The **prefix** shall resolve to denote either a package [(including the current instance of a generic package, or a rename of a package)], or an enclosing named construct.
- 12 • The **selector_name** shall resolve to denote a declaration that occurs immediately within the declarative region of the package or enclosing construct [(the declaration shall be visible at the place of the expanded name — see 8.3)]. The expanded name denotes that declaration.
- 12.a **Ramification:** Hence, a library unit or subunit can use an expanded name to refer to the declarations within the private part of its parent unit, as well as to other children that have been mentioned in **with_clauses**.
- 13 • If the **prefix** does not denote a package, then it shall be a **direct_name** or an expanded name, and it shall resolve to denote a program unit (other than a package), the current instance of a type, a **block_statement**, a **loop_statement**, or an **accept_statement** (in the case of an **accept_statement** or **entry_body**, no family index is allowed); the expanded name shall occur within the declarative region of this construct. Further, if this construct is a callable construct and the **prefix** denotes more than one such enclosing callable construct, then the expanded name is ambiguous, independently of the **selector_name**.

Legality Rules

- 13.1/2 *{AI95-00252-01}* *{AI95-00407-01}* For a subprogram whose first parameter is an access parameter, the prefix of any prefixed view shall denote an aliased view of an object.
- 13.2/2 *{AI95-00407-01}* For a subprogram whose first parameter is of mode **in out** or **out**, or of an anonymous access-to-variable type, the prefix of any prefixed view shall denote a variable.
- 13.a/2 **Reason:** We want calls through a prefixed view and through a normal view to have the same legality. Thus, the implicit 'Access in this new notation needs the same legality check that an explicit 'Access would have. Similarly, we need to prohibit the object from being constant if the first parameter of the subprogram is **in out**, because that is (obviously) prohibited for passing a normal parameter.

Dynamic Semantics

The evaluation of a `selected_component` includes the evaluation of the prefix. 14

For a `selected_component` that denotes a component of a variant, a check is made that the values of the discriminants are such that the value or object denoted by the prefix has this component. The exception `Constraint_Error` is raised if this check fails. 15

Examples

Examples of selected components: 16

```
{AI95-00252-01} {AI95-00407-01} Tomorrow.Month -- a record component (see 3.8) 17/2
Next_Car.Owner -- a record component (see 3.10.1)
Next_Car.Owner.Age -- a record component (see 3.10.1)
-- the previous two lines involve implicit dereferences
Writer.Unit -- a record component (a discriminant) (see 3.8.1)
Min_Cell(H).Value -- a record component of the result (see 6.1)
-- of the function call Min_Cell(H)
Cashier.Append -- a prefixed view of a procedure (see 3.9.4)
Control.Seize -- an entry of a protected object (see 9.4)
Pool(K).Write -- an entry of the task Pool(K) (see 9.4)
```

Examples of expanded names: 18

```
Key_Manager."<" -- an operator of the visible part of a package (see 7.3.1) 19
Dot_Product.Sum -- a variable declared in a function body (see 6.1)
Buffer.Pool -- a variable declared in a protected unit (see 9.11)
Buffer.Read -- an entry of a protected unit (see 9.11)
Swap.Temp -- a variable declared in a block statement (see 5.6)
Standard.Booleam -- the name of a predefined type (see A.1)
```

Extensions to Ada 83

We now allow an expanded name to use a prefix that denotes a rename of a package, even if the selector is for an entity local to the body or private part of the package, so long as the entity is visible at the place of the reference. This eliminates a preexisting anomaly where references in a package body may refer to declarations of its visible part but not those of its private part or body when the prefix is a rename of the package. 19.a

Wording Changes from Ada 83

The syntax rule for `selector_name` is new. It is used in places where visibility, but not necessarily direct visibility, is required. See 4.1, “Names” for more information. 19.b

The description of dereferencing an access type has been moved to 4.1, “Names”; `name.all` is no longer considered a `selected_component`. 19.c

The rules have been restated to be consistent with our new terminology, to accommodate class-wide types, etc. 19.d

Extensions to Ada 95

{AI95-00252-01} The prefixed view notation for tagged objects is new. This provides a similar notation to that used in other popular languages, and also reduces the need for `use_clauses`. This is sometimes known as “distinguished receiver notation”. 19.e/2

Given the following definitions for a tagged type T: 19.f/2

```
procedure Do_Something (Obj : in out T; Count : in Natural); 19.g/2
procedure Do_Something_Else (Obj : access T; Flag : in Boolean);
My_Object : aliased T;
```

the following calls are equivalent: 19.h/2

```
Do_Something (My_Object, Count => 10); 19.i/2
My_Object.Do_Something (Count => 10);
```

as are the following calls: 19.j/2

```
Do_Something_Else (My_Object'Access, Flag => True); 19.k/2
My_Object.Do_Something_Else (Flag => True);
```

- 19.I/3 {AI05-0090-1} **Correction:** Corrected the definition of a prefixed view to ignore the implicit subprograms declared for “implemented by” entries and protected subprograms.

4.1.4 Attributes

- 1 [An *attribute* is a characteristic of an entity that can be queried via an `attribute_reference` or a `range_attribute_reference`.]

Syntax

- 2 `attribute_reference ::= prefix'attribute_designator`
 3/2 {AI05-0004-1} `attribute_designator ::=`
 `identifier[(static_expression)]`
 | `Access` | `Delta` | `Digits` | `Mod`
 4 `range_attribute_reference ::= prefix'range_attribute_designator`
 5 `range_attribute_designator ::= Range[(static_expression)]`

Name Resolution Rules

- 6 In an `attribute_reference`, if the `attribute_designator` is for an attribute defined for (at least some) objects of an access type, then the `prefix` is never interpreted as an `implicit_dereference`; otherwise (and for all `range_attribute_references`), if the type of the name within the `prefix` is of an access type, the `prefix` is interpreted as an `implicit_dereference`. Similarly, if the `attribute_designator` is for an attribute defined for (at least some) functions, then the `prefix` is never interpreted as a `parameterless_function_call`; otherwise (and for all `range_attribute_references`), if the `prefix` consists of a name that denotes a function, it is interpreted as a `parameterless_function_call`.
- 6.a **Discussion:** The first part of this rule is essentially a "preference" against implicit dereference, so that it is possible to ask for, say, 'Size of an access object, without automatically getting the size of the object designated by the access object. This rule applies to 'Access, 'Unchecked_Access, 'Size, and 'Address, and any other attributes that are defined for at least some access objects.
- 6.b The second part of this rule implies that, for a parameterless function F, F'Address is the address of F, whereas F'Size is the size of the anonymous constant returned by F.
- 6.c/1 We normally talk in terms of expected type or profile for name resolution rules, but we don't do this for attributes because certain attributes are legal independent of the type or the profile of the `prefix`.
- 6.d/2 {AI95-00114-01} Other than the rules given above, the Name Resolution Rules for the `prefix` of each attribute are defined as Name Resolution Rules for that attribute. If no such rules are defined, then no context at all should be used when resolving the `prefix`. In particular, any knowledge about the kind of entities required must not be used for resolution unless that is required by Name Resolution Rules. This matters in obscure cases; for instance, given the following declarations:
- 6.e/2 `function Get_It return Integer is ... -- (1)`
 `function Get_It return Some_Record_Type is ... -- (2)`
- 6.f/2 the following `attribute_reference` cannot be resolved and is illegal:
- 6.g/2 `if Get_It'Valid then`
- 6.h/3 {AI05-0005-1} even though the `Valid` attribute is only defined for objects of scalar types, and thus cannot be applied to the result of function (2). That information cannot be used to resolve the `prefix`. The same would be true if (2) had been a procedure; even though the procedure does not denote an object, the `attribute_reference` is still illegal.
- 7 The expression, if any, in an `attribute_designator` or `range_attribute_designator` is expected to be of any integer type.

Legality Rules

- 8 The expression, if any, in an `attribute_designator` or `range_attribute_designator` shall be static.

Static Semantics

{AI05-0006-1} An `attribute_reference` denotes a value, an object, a subprogram, or some other kind of program entity. For an `attribute_reference` that denotes a value or an object, if its type is scalar, then its nominal subtype is the base subtype of the type; if its type is tagged, its nominal subtype is the first subtype of the type; otherwise, its nominal subtype is a subtype of the type without any constraint or `null_exclusion`. Similarly, unless explicitly specified otherwise, for an `attribute_reference` that denotes a function, when its result type is scalar, its result subtype is the base subtype of the type, when its result type is tagged, the result subtype is the first subtype of the type, and when the result type is some other type, the result subtype is a subtype of the type without any constraint or `null_exclusion`. 9/3

Ramification: The attributes defined by the language are summarized in K.2. Implementations can define additional attributes. 9.a

Discussion: {AI05-0006-1} The nominal subtype is primarily a concern when an `attribute_reference`, or a call on an `attribute_reference`, is used as the expression of a case statement, due to the full coverage requirement based on the nominal subtype. For nondiscrete cases, we define the nominal subtype mainly for completeness. Implementations may specify otherwise for implementation-defined attribute functions. 9.b/3

The rule is written to match the meaning of the italicized *T* in the definition of attributes such as `Input`; see 4.5.1. 9.c/3

To be honest: {AI05-0006-1} We don't worry about the fact that “base subtype” is not explicitly defined for the universal types. Since it is not possible to constrain a universal numeric type, all subtypes are unconstrained, and hence can be considered base subtypes. The wording above could be altered to bypass this issue, but it doesn't seem necessary, since universal integer is handled specially in the rules for case expression full coverage, and we don't allow user-defined functions for attribute functions whose result type is universal. 9.d/3

[A `range_attribute_reference` `X'Range(N)` is equivalent to the `range` `X'First(N) .. X'Last(N)`, except that the prefix is only evaluated once. Similarly, `X'Range` is equivalent to `X'First .. X'Last`, except that the prefix is only evaluated once.] 10

Dynamic Semantics

The evaluation of an `attribute_reference` (or `range_attribute_reference`) consists of the evaluation of the prefix. 11

Implementation Permissions

{8652/0015} {AI95-00093-01} An implementation may provide implementation-defined attributes; the identifier for an implementation-defined attribute shall differ from those of the language-defined attributes unless supplied for compatibility with a previous edition of this International Standard. 12/1

Implementation defined: Implementation-defined attributes. 12.a

Ramification: They cannot be reserved words because reserved words are not legal identifiers. 12.b

The semantics of implementation-defined attributes, and any associated rules, are, of course, implementation defined. For example, the implementation defines whether a given implementation-defined attribute can be used in a static expression. 12.c

{8652/0015} {AI95-00093-01} Implementations are allowed to support the `Small` attribute for floating types, as this was defined in Ada 83, even though the name would conflict with a language-defined attribute. 12.c.1/1

NOTES

4 Attributes are defined throughout this International Standard, and are summarized in K.2. 13

5 {AI95-00235} In general, the name in a prefix of an `attribute_reference` (or a `range_attribute_reference`) has to be resolved without using any context. However, in the case of the `Access` attribute, the expected type for the `attribute_reference` has to be a single access type, and the resolution of the name can use the fact that the type of the object or the profile of the callable entity denoted by the prefix has to match the designated type or be type conformant with the designated profile of the access type. 14/2

Proof: {AI95-00235} In the general case, there is no “expected type” for the prefix of an `attribute_reference`. In the special case of `'Access`, there is an “expected type” or “expected profile” for the prefix. 14.a/2

Reason: `'Access` is a special case, because without it, it would be very difficult to take `'Access` of an overloaded subprogram. 14.b

Examples

15 Examples of attributes:

16	Color'First	-- minimum value of the enumeration type Color	(see 3.5.1)
	Rainbow'Base'First	-- same as Color'First	(see 3.5.1)
	Real'Digits	-- precision of the type Real	(see 3.5.7)
	Board'Last(2)	-- upper bound of the second dimension of Board	(see 3.6.1)
	Board'Range(1)	-- index range of the first dimension of Board	(see 3.6.1)
	Pool(K)'Terminated	-- True if task Pool(K) is terminated	(see 9.1)
	Date'Size	-- number of bits for records of type Date	(see 3.8)
	Message'Address	-- address of the record variable Message	(see 3.7.1)

Extensions to Ada 83

- 16.a We now uniformly treat X'Range as X'First..X'Last, allowing its use with scalar subtypes.
- 16.b We allow any integer type in the *static_expression* of an attribute designator, not just a value of *universal_integer*. The preference rules ensure upward compatibility.

Wording Changes from Ada 83

- 16.c We use the syntactic category *attribute_reference* rather than simply "attribute" to avoid confusing the name of something with the thing itself.
- 16.d The syntax rule for *attribute_reference* now uses *identifier* instead of *simple_name*, because attribute identifiers are not required to follow the normal visibility rules.
- 16.e We now separate *attribute_reference* from *range_attribute_reference*, and enumerate the reserved words that are legal attribute or range attribute designators. We do this because *identifier* no longer includes reserved words.
- 16.f The Ada 95 name resolution rules are a bit more explicit than in Ada 83. The Ada 83 rule said that the "meaning of the prefix of an attribute must be determinable independently of the attribute designator and independently of the fact that it is the prefix of an attribute." That isn't quite right since the meaning even in Ada 83 embodies whether or not the prefix is interpreted as a parameterless function call, and in Ada 95, it also embodies whether or not the prefix is interpreted as an *implicit_dereference*. So the attribute designator does make a difference — just not much.
- 16.g Note however that if the attribute designator is *Access*, it makes a big difference in the interpretation of the prefix (see 3.10.2).

Wording Changes from Ada 95

- 16.h/2 {8652/0015} {AI95-00093-01} **Corrigendum:** The wording was changed to allow implementations to continue to implement the Ada 83 Small attribute. This was always intended to be allowed.
- 16.i/2 {AI95-00235-01} The note about resolving prefixes of attributes was updated to reflect that the prefix of an *Access* attribute now has an expected type (see 3.10.2).

Wording Changes from Ada 2005

- 16.j/3 {AI05-0006-1} **Correction:** Defined the nominal subtype of an *attribute_reference* to close a minor language hole.

4.1.5 User-Defined References

Static Semantics

- 1/3 {AI05-0139-2} Given a discriminated type *T*, the following type-related operational aspect may be specified:
- 2/3 **Implicit_Dereference**
This aspect is specified by a name that denotes an access discriminant declared for the type *T*.
- 2.a/3 **Aspect Description for Implicit_Dereference:** Mechanism for user-defined implicit **.all**.
- 3/3 {AI05-0139-2} A (view of a) type with a specified *Implicit_Dereference* aspect is a *reference type*. A *reference object* is an object of a reference type. The discriminant named by the *Implicit_Dereference* aspect is the *reference discriminant* of the reference type or reference object. [A *generalized_reference*

is a **name** that identifies a reference object, and denotes the object or subprogram designated by the reference discriminant of the reference object.]

Glossary entry: A reference type is one that has user-defined behavior for “.**all**”, defined by the `Implicit_Dereference` aspect. 3.a.1/3

Syntax

{AI05-0139-2} `generalized_reference ::= reference_object_name` 4/3

Name Resolution Rules

{AI05-0139-2} {AI05-0269-1} The expected type for the `reference_object_name` in a `generalized_reference` is any reference type. 5/3

Static Semantics

{AI05-0139-2} A `generalized_reference` denotes a view equivalent to that of a dereference of the reference discriminant of the reference object. 6/3

{AI05-0139-2} Given a reference type *T*, the `Implicit_Dereference` aspect is inherited by descendants of type *T* if not overridden. If a descendant type constrains the value of the reference discriminant of *T* by a new discriminant, that new discriminant is the reference discriminant of the descendant. [If the descendant type constrains the value of the reference discriminant of *T* by an expression other than the name of a new discriminant, a `generalized_reference` that identifies an object of the descendant type denotes the object or subprogram designated by the value of this constraining expression.] 7/3

Dynamic Semantics

{AI05-0139-2} The evaluation of a `generalized_reference` consists of the evaluation of the `reference_object_name` and a determination of the object or subprogram designated by the reference discriminant of the named reference object. A check is made that the value of the reference discriminant is not the null access value. `Constraint_Error` is raised if this check fails. The `generalized_reference` denotes the object or subprogram designated by the value of the reference discriminant of the named reference object. 8/3

Examples

```
{AI05-0268-1} type Barrel is tagged ... -- holds objects of type Element 9/3
{AI05-0139-2} {AI05-0299-2} type Ref_Element(Data : access Element) is limited 10/3
private
with Implicit_Dereference => Data;
-- This Ref_Element type is a "reference" type.
-- "Data" is its reference discriminant.

{AI05-0139-2} {AI05-0268-1} function Find (B : aliased in out Barrel; Key : String) 11/3
return Ref_Element;
-- Return a reference to an element of a barrel.

{AI05-0268-1} {AI05-0299-2} B: aliased Barrel; 12/3
{AI05-0139-2} ... 13/3
{AI05-0139-2} {AI05-0268-1} Find (B, "grape") := Element'(...); -- Assign through a 14/3
reference.
{AI05-0139-2} {AI05-0268-1} -- This is equivalent to: 15/3
Find (B, "grape").Data.all := Element'(...);
```

Extensions to Ada 2005

{AI05-0139-2} The aspect `Implicit_Dereference` and the `generalized_reference` are new. 15.a/3

4.1.6 User-Defined Indexing

Static Semantics

- 1/3 {AI05-0139-2} Given a tagged type T , the following type-related, operational aspects may be specified:
- 2/3 Constant_Indexing
 This aspect shall be specified by a name that denotes one or more functions declared immediately within the same declaration list in which T is declared. All such functions shall have at least two parameters, the first of which is of type T or T Class, or is an access-to-constant parameter with designated type T or T Class.
- 2.a/3 **Aspect Description for Constant_Indexing:** Defines function(s) to implement user-defined indexed_components.
- 3/3 Variable_Indexing
 This aspect shall be specified by a name that denotes one or more functions declared immediately within the same declaration list in which T is declared. All such functions shall have at least two parameters, the first of which is of type T or T Class, or is an access parameter with designated type T or T Class. All such functions shall have a return type that is a reference type (see 4.1.5), whose reference discriminant is of an access-to-variable type.
- 3.a/3 **Reason:** We require these functions to return a reference type so that the object returned from the function can act like a variable. We need no similar rule for Constant_Indexing, since all functions return constant objects.
- 3.b/3 **Aspect Description for Variable_Indexing:** Defines function(s) to implement user-defined indexed_components.
- 4/3 These aspects are inherited by descendants of T (including the class-wide type T Class). [The aspects shall not be overridden, but the functions they denote may be.]
- 4.a/3 **Ramification:** Indexing can be provided for multiple index types by overloading routines with different parameter profiles. For instance, the map containers provide indexing on both cursors and keys by providing pairs of overloaded routines to the Constant_Indexing and Variable_Indexing aspects.
- 5/3 {AI05-0139-2} {AI05-0292-1} An *indexable container type* is (a view of) a tagged type with at least one of the aspects Constant_Indexing or Variable_Indexing specified. An *indexable container object* is an object of an indexable container type. [A `generalized_indexing` is a name that denotes the result of calling a function named by a Constant_Indexing or Variable_Indexing aspect.]
- 5.a.1/3 **Glossary entry:** An indexable container type is one that has user-defined behavior for indexing, via the Constant_Indexing or Variable_Indexing aspects.

Legality Rules

- 6/3 {AI05-0139-2} The Constant_Indexing or Variable_Indexing aspect shall not be specified:
- 7/3
- on a derived type if the parent type has the corresponding aspect specified or inherited; or
 - on a full_type_declaration if the type has a tagged partial view.
- 8/3
- 9/3 In addition to the places where Legality Rules normally apply (see 12.3), these rules apply also in the private part of an instance of a generic unit.
- 9.a/3 **Ramification:** In order to enforce these rules without breaking privacy, we cannot allow a tagged private type to have hidden indexing aspects. There is no problem if the private type is not tagged (as the indexing aspects cannot be specified on descendants in that case).
- 9.b/3 We don't need an assume-the-worst rule as deriving from formal tagged type is not allowed in generic bodies.

Syntax

- 10/3 {AI05-0139-2} {AI05-0292-1} `generalized_indexing ::= indexable_container_object_prefix actual_parameter_part`

Name Resolution Rules

{AI05-0139-2} {AI05-0292-1} The expected type for the *indexable_container_object_prefix* of a *generalized_indexing* is any indexable container type. 11/3

{AI05-0139-2} {AI05-0292-1} If the *Constant_Indexing* aspect is specified for the type of the *indexable_container_object_prefix* of a *generalized_indexing*, then the *generalized_indexing* is interpreted as a *constant_indexing* under the following circumstances: 12/3

- when the *Variable_Indexing* aspect is not specified for the type of the *indexable_container_object_prefix*; 13/3
- when the *indexable_container_object_prefix* denotes a constant; 14/3
- when the *generalized_indexing* is used within a primary where a name denoting a constant is permitted. 15/3

Ramification: This means it is not interpreted as a constant indexing for the *variable_name* in the LHS of an assignment (not inside a primary), nor for the name used for an *out* or *in out* parameter (not allowed to be a constant), nor for the name in an object renaming (not inside a primary), unless there is no *Variable_Indexing* aspect defined. 15.a/3

Otherwise, the *generalized_indexing* is interpreted as a *variable_indexing*. 16/3

When a *generalized_indexing* is interpreted as a constant (or variable) indexing, it is equivalent to a call on a prefixed view of one of the functions named by the *Constant_Indexing* (or *Variable_Indexing*) aspect of the type of the *indexable_container_object_prefix* with the given *actual_parameter_part*, and with the *indexable_container_object_prefix* as the prefix of the prefixed view. 17/3

Ramification: In other words, the *generalized_indexing* is equivalent to: 17.a/3

indexable_container_object_prefix.*Indexing* *actual_parameter_part* 17.b/3

where *Indexing* is the name specified for the *Constant_Indexing* or *Variable_Indexing* aspect. 17.c/3

Examples

```
{AI05-0268-1} {AI05-0292-1} type Indexed_Barrel is tagged ... 18/3
with Variable_Indexing => Find;
-- Indexed_Barrel is an indexable container type,
-- Find is the generalized indexing operation.
```

```
{AI05-0268-1} function Find (B : aliased in out Indexed_Barrel; Key : String) 19/3
return Ref_Element;
-- Return a reference to an element of a barrel (see 4.1.5).
```

```
{AI05-0268-1} IB: aliased Indexed_Barrel; 20/3
```

```
{AI05-0268-1} -- All of the following calls are then equivalent: 21/3
Find (IB,"pear").Data.all := Element' (...); -- Traditional call
IB.Find ("pear").Data.all := Element' (...); -- Call of prefixed view
IB.Find ("pear")          := Element' (...); -- Implicit dereference (see 4.1.5)
IB ("pear")               := Element' (...); -- Implicit indexing and dereference
IB ("pear").Data.all      := Element' (...); -- Implicit indexing only
```

Extensions to Ada 2005

{AI05-0139-2} Aspects *Constant_Indexing* and *Variable_Indexing*, and the *generalized_indexing* syntax are new. 21.a/3

4.2 Literals

[A *literal* represents a value literally, that is, by means of notation suited to its kind.] A literal is either a *numeric_literal*, a *character_literal*, the literal **null**, or a *string_literal*. 1

Discussion: An enumeration literal that is an identifier rather than a *character_literal* is not considered a *literal* in the above sense, because it involves no special notation “suited to its kind.” It might more properly be called an *enumeration_identifier*, except for historical reasons. 1.a

Name Resolution Rules

2/2 *This paragraph was deleted. {AI95-00230-01}*

3 For a name that consists of a `character_literal`, either its expected type shall be a single character type, in which case it is interpreted as a parameterless `function_call` that yields the corresponding value of the character type, or its expected profile shall correspond to a parameterless function with a character result type, in which case it is interpreted as the name of the corresponding parameterless function declared as part of the character type's definition (see 3.5.1). In either case, the `character_literal` denotes the `enumeration_literal_specification`.

3.a **Discussion:** See 4.1.3 for the resolution rules for a `selector_name` that is a `character_literal`.

4 The expected type for a primary that is a `string_literal` shall be a single string type.

Legality Rules

5 A `character_literal` that is a name shall correspond to a `defining_character_literal` of the expected type, or of the result type of the expected profile.

6 For each character of a `string_literal` with a given expected string type, there shall be a corresponding `defining_character_literal` of the component type of the expected string type.

7/2 *This paragraph was deleted. {AI95-00230-01} {AI95-00231-01}*

Static Semantics

8/2 *{AI95-00230-01}* An integer literal is of type *universal_integer*. A real literal is of type *universal_real*. The literal **null** is of type *universal_access*.

Dynamic Semantics

9 The evaluation of a numeric literal, or the literal **null**, yields the represented value.

10 The evaluation of a `string_literal` that is a primary yields an array value containing the value of each character of the sequence of characters of the `string_literal`, as defined in 2.6. The bounds of this array value are determined according to the rules for `positional_array_aggregates` (see 4.3.3), except that for a null string literal, the upper bound is the predecessor of the lower bound.

11 For the evaluation of a `string_literal` of type *T*, a check is made that the value of each character of the `string_literal` belongs to the component subtype of *T*. For the evaluation of a null string literal, a check is made that its lower bound is greater than the lower bound of the base range of the index type. The exception `Constraint_Error` is raised if either of these checks fails.

11.a **Ramification:** The checks on the characters need not involve more than two checks altogether, since one need only check the characters of the string with the lowest and highest position numbers against the range of the component subtype.

NOTES

12 6 Enumeration literals that are `identifiers` rather than `character_literals` follow the normal rules for `identifiers` when used in a `name` (see 4.1 and 4.1.3). `Character_literals` used as `selector_names` follow the normal rules for expanded names (see 4.1.3).

Examples

13 *Examples of literals:*

14 3.14159_26536 -- a real literal
 1_345 -- an integer literal
 'A' -- a character literal
 "Some Text" -- a string literal

Incompatibilities With Ada 83

Because `character_literals` are now treated like other literals, in that they are resolved using context rather than depending on direct visibility, additional qualification might be necessary when passing a `character_literal` to an overloaded subprogram. 14.a

Extensions to Ada 83

`Character_literals` are now treated analogously to `null` and `string_literals`, in that they are resolved using context, rather than their content; the declaration of the corresponding `defining_character_literal` need not be directly visible. 14.b

Wording Changes from Ada 83

Name Resolution rules for enumeration literals that are not `character_literals` are not included anymore, since they are neither syntactically nor semantically "literals" but are rather names of parameterless functions. 14.c

Extensions to Ada 95

{AI95-00230-01} {AI95-00231-01} `Null` now has type `universal_access`, which is similar to other literals. `Null` can be used with anonymous access types. 14.d/2

4.3 Aggregates

[An *aggregate* combines component values into a composite value of an array type, record type, or record extension.] 1

Syntax

`aggregate ::= record_aggregate | extension_aggregate | array_aggregate` 2

Name Resolution Rules

{AI95-00287-01} The expected type for an `aggregate` shall be a single array type, record type, or record extension. 3/2

Discussion: See 8.6, “The Context of Overload Resolution” for the meaning of “shall be a single ... type.” 3.a

Ramification: {AI05-0005-1} There are additional rules for each kind of aggregate. These aggregate rules are additive; a legal expression needs to satisfy all of the applicable rules. That means the rule given here must be satisfied even when it is syntactically possible to tell which specific kind of aggregate is being used. 3.b/3

Legality Rules

An aggregate shall not be of a class-wide type. 4

Ramification: When the expected type in some context is class-wide, an aggregate has to be explicitly qualified by the specific type of value to be created, so that the expected type for the aggregate itself is specific. 4.a

Discussion: We used to disallow aggregates of a type with unknown discriminants. However, that was unnecessarily restrictive in the case of an extension aggregate, and irrelevant to a record aggregate (since a type that is legal for a record aggregate could not possibly have unknown discriminants) and to an array aggregate (the only specific types that can have unknown discriminants are private types, private extensions, and types derived from them). 4.b

Dynamic Semantics

For the evaluation of an `aggregate`, an anonymous object is created and values for the components or ancestor part are obtained (as described in the subsequent subclause for each kind of the `aggregate`) and assigned into the corresponding components or ancestor part of the anonymous object. Obtaining the values and the assignments occur in an arbitrary order. The value of the `aggregate` is the value of this object. 5

Discussion: The ancestor part is the set of components inherited from the ancestor type. The syntactic category `ancestor_part` is the expression or `subtype_mark` that specifies how the ancestor part of the anonymous object should be initialized. 5.a

- 5.b **Ramification:** The assignment operations do the necessary value adjustment, as described in 7.6. Note that the value as a whole is not adjusted — just the subcomponents (and ancestor part, if any). 7.6 also describes when this anonymous object is finalized.
- 5.c If the `ancestor_part` is a `subtype_mark` the Initialize procedure for the ancestor type is applied to the ancestor part after default-initializing it, unless the procedure is abstract, as described in 7.6. The Adjust procedure for the ancestor type is not called in this case, since there is no assignment to the ancestor part as a whole.
- 6 If an aggregate is of a tagged type, a check is made that its value belongs to the first subtype of the type. `Constraint_Error` is raised if this check fails.
- 6.a **Ramification:** This check ensures that no values of a tagged type are ever outside the first subtype, as required for inherited dispatching operations to work properly (see 3.4). This check will always succeed if the first subtype is unconstrained. This check is not extended to untagged types to preserve upward compatibility.

Extensions to Ada 83

- 6.b We now allow `extension_aggregates`.

Wording Changes from Ada 83

- 6.c We have adopted new wording for expressing the rule that the type of an aggregate shall be determinable from the outside, though using the fact that it is nonlimited record (extension) or array.
- 6.d An aggregate now creates an anonymous object. This is necessary so that controlled types will work (see 7.6).

Incompatibilities With Ada 95

- 6.e/2 *{AI95-00287-01}* In Ada 95, a limited type is not considered when resolving an aggregate. Since Ada 2005 now allows limited aggregates, we can have incompatibilities. For example:
- 6.f/2

```
type Lim is limited
  record
    Comp: Integer;
  end record;
```
- 6.g/2

```
type Not_Lim is
  record
    Comp: Integer;
  end record;
```
- 6.h/2

```
procedure P(X: Lim);
procedure P(X: Not_Lim);
```
- 6.i/2

```
P((Comp => 123)); -- Illegal in Ada 2005, legal in Ada 95
```
- 6.j/2 The call to P is ambiguous in Ada 2005, while it would not be ambiguous in Ada 95 as the aggregate could not have a limited type. Qualifying the aggregate will eliminate any ambiguity. This construction would be rather confusing to a maintenance programmer, so it should be avoided, and thus we expect it to be rare.

Extensions to Ada 95

- 6.k/2 *{AI95-00287-01}* Aggregates can be of a limited type.

4.3.1 Record Aggregates

- 1 [In a `record_aggregate`, a value is specified for each component of the record or record extension value, using either a named or a positional association.]

Syntax

- 2 `record_aggregate ::= (record_component_association_list)`
- 3 `record_component_association_list ::=`
`record_component_association {, record_component_association}`
`| null record`
- 4/2 *{AI95-00287-01}* `record_component_association ::=`
`[component_choice_list =>] expression`
`| component_choice_list => <>`

<pre> component_choice_list ::= component_selector_name { component_selector_name } others </pre>	5
<p>A <code>record_component_association</code> is a <i>named component association</i> if it has a <code>component_choice_list</code>; otherwise, it is a <i>positional component association</i>. Any positional component associations shall precede any named component associations. If there is a named association with a <code>component_choice_list</code> of others, it shall come last.</p>	6
<p>Discussion: These rules were implied by the BNF in an early version of the RM9X, but it made the grammar harder to read, and was inconsistent with how we handle discriminant constraints. Note that for array aggregates we still express some of the rules in the grammar, but array aggregates are significantly different because an array aggregate is either all positional (with a possible others at the end), or all named.</p>	6.a
<p>In the <code>record_component_association_list</code> for a <code>record_aggregate</code>, if there is only one association, it shall be a named association.</p>	7
<p>Reason: {AI05-0264-1} Otherwise, the construct would be interpreted as a parenthesized expression. This is considered a syntax rule, since it is relevant to overload resolution. We choose not to express it with BNF so we can share the definition of <code>record_component_association_list</code> in both <code>record_aggregate</code> and <code>extension_aggregate</code>.</p>	7.a/3
<p>Ramification: The <code>record_component_association_list</code> of an <code>extension_aggregate</code> does not have such a restriction.</p>	7.b
<i>Name Resolution Rules</i>	
<p>{AI95-00287-01} The expected type for a <code>record_aggregate</code> shall be a single record type or record extension.</p>	8/2
<p>Ramification: This rule is used to resolve whether an aggregate is an <code>array_aggregate</code> or a <code>record_aggregate</code>. The presence of a with is used to resolve between a <code>record_aggregate</code> and an <code>extension_aggregate</code>.</p>	8.a
<p>For the <code>record_component_association_list</code> of a <code>record_aggregate</code>, all components of the composite value defined by the aggregate are <i>needed</i>]; for the association list of an <code>extension_aggregate</code>, only those components not determined by the ancestor expression or subtype are needed (see 4.3.2).] Each <code>selector_name</code> in a <code>record_component_association</code> shall denote a needed component [(including possibly a discriminant)].</p>	9
<p>Ramification: For the association list of a <code>record_aggregate</code>, “needed components” includes every component of the composite value, but does not include those in unchosen variants (see AI83-309). If there are variants, then the value specified for the discriminant that governs them determines which variant is chosen, and hence which components are needed.</p>	9.a
<p>If an extension defines a new <code>known_discriminant_part</code>, then all of its discriminants are needed in the component association list of an extension aggregate for that type, even if the discriminants have the same names and types as discriminants of the type of the ancestor expression. This is necessary to ensure that the positions in the <code>record_component_association_list</code> are well defined, and that discriminants that govern <code>variant_parts</code> can be given by static expressions.</p>	9.b
<p>The expected type for the expression of a <code>record_component_association</code> is the type of the <i>associated</i> component(s); the associated component(s) are as follows:</p>	10
<ul style="list-style-type: none"> • For a positional association, the component [(including possibly a discriminant)] in the corresponding relative position (in the declarative region of the type), counting only the needed components; 	11
<p>Ramification: This means that for an association list of an <code>extension_aggregate</code>, only noninherited components are counted to determine the position.</p>	11.a
<p>{AI05-0005-1} For a derived type (including type extensions), the order of declaration is defined in 3.4, “Derived Types and Classes”. In particular, all discriminants come first, regardless of whether they are defined for the parent type or are newly added to the derived type.</p>	11.b/3
<ul style="list-style-type: none"> • For a named association with one or more <code>component_selector_names</code>, the named component(s); 	12
<ul style="list-style-type: none"> • For a named association with the reserved word others, all needed components that are not associated with some previous association. 	13

Legality Rules

- 14 If the type of a `record_aggregate` is a record extension, then it shall be a descendant of a record type, through one or more record extensions (and no private extensions).
- 15/3 {AI05-0016-1} The reserved words **null record** may appear only if there are no components needed in a given `record_component_association_list`.
- 15.a **Ramification:** For example, "(**null record**)" is a `record_aggregate` for a null record type. Similarly, "(T(A) **with null record**)" is an `extension_aggregate` for a type defined as a null record extension of T.
- 15.b/3 {AI05-0016-1} If no components are needed and **null record** is not used, the `record_component_association` must necessarily be **others** \Rightarrow \diamond , as that is the only `record_component_association` that does not require an associated component.
- 16/3 {AI95-00287-01} {AI05-0199-1} Each `record_component_association` other than an **others** choice with a \diamond shall have at least one associated component, and each needed component shall be associated with exactly one `record_component_association`. If a `record_component_association` with an `expression` has two or more associated components, all of them shall be of the same type, or all of them shall be of anonymous access types whose subtypes statically match.
- 16.a/2 **Ramification:** {AI95-00287-01} These rules apply to an association with an **others** choice with an `expression`. An **others** choice with a \diamond can match zero components or several components with different types.
- 16.b/2 **Reason:** {AI95-00287-01} Without these rules, there would be no way to know what was the expected type for the `expression` of the association. Note that some of the rules do not apply to \diamond associations, as we do not need to resolve anything. We allow **others** \Rightarrow \diamond to match no components as this is similar to array aggregates. That means that (**others** \Rightarrow \diamond) always represents a default-initialized record or array value.
- 16.c **Discussion:** AI83-00244 also requires that the `expression` shall be legal for each associated component. This is because even though two components have the same type, they might have different subtypes. Therefore, the legality of the `expression`, particularly if it is an array aggregate, might differ depending on the associated component's subtype. However, we have relaxed the rules on array aggregates slightly for Ada 95, so the staticness of an applicable index constraint has no effect on the legality of the array aggregate to which it applies. See 4.3.3. This was the only case (that we know of) where a subtype provided by context affected the legality of an `expression`.
- 16.d **Ramification:** The rule that requires at least one associated component for each `record_component_association` implies that there can be no extra associations for components that don't exist in the composite value, or that are already determined by the ancestor `expression` or subtype of an `extension_aggregate`.
- 16.e The second part of the first sentence ensures that no needed components are left out, nor specified twice.
- 17/3 {AI05-0220-1} The value of a discriminant that governs a `variant_part P` shall be given by a static `expression`, unless `P` is nested within a `variant V` that is not selected by the discriminant value governing the `variant_part` enclosing `V`.
- 17.a **Ramification:** This `expression` might either be given within the aggregate itself, or in a constraint on the parent subtype in a `derived_type_definition` for some ancestor of the type of the aggregate.
- 17.1/2 {AI95-00287-01} A `record_component_association` for a discriminant without a `default_expression` shall have an `expression` rather than \diamond .
- 17.b/2 **Reason:** A discriminant must always have a defined value, but \diamond means uninitialized for a discrete type unless the component has a default value.

Dynamic Semantics

- 18 The evaluation of a `record_aggregate` consists of the evaluation of the `record_component_association_list`.
- 19 For the evaluation of a `record_component_association_list`, any per-object constraints (see 3.8) for components specified in the association list are elaborated and any `expressions` are evaluated and converted to the subtype of the associated component. Any constraint elaborations and `expression` evaluations (and conversions) occur in an arbitrary order, except that the `expression` for a discriminant is evaluated (and converted) prior to the elaboration of any per-object constraint that depends on it, which in

turn occurs prior to the evaluation and conversion of the expression for the component with the per-object constraint.

Ramification: The conversion in the first rule might raise `Constraint_Error`. 19.a

Discussion: This check in the first rule presumably happened as part of the dependent compatibility check in Ada 83. 19.b

{AI95-00287-01} For a `record_component_association` with an expression, the expression defines the value for the associated component(s). For a `record_component_association` with $\langle \rangle$, if the `component_declaration` has a `default_expression`, that `default_expression` defines the value for the associated component(s); otherwise, the associated component(s) are initialized by default as for a stand-alone object of the component subtype (see 3.3.1). 19.1/2

The expression of a `record_component_association` is evaluated (and converted) once for each associated component. 20

Ramification: {AI05-0005-1} We don't need similar language for $\langle \rangle$, as we're considering the value of $\langle \rangle$ for each individual component. Each component has its own default expression or its own default initialization (they can be different for each component; the components even could have different types), and each one has to be evaluated. So there is no need to repeat that. 20.a/3

NOTES

7 For a `record_aggregate` with positional associations, expressions specifying discriminant values appear first since the `known_discriminant_part` is given first in the declaration of the type; they have to be in the same order as in the `known_discriminant_part`. 21

Examples

Example of a record aggregate with positional associations: 22

```
(4, July, 1776) -- see 3.8 23
```

Examples of record aggregates with named associations: 24

```
(Day => 4, Month => July, Year => 1776) 25
```

```
(Month => July, Day => 4, Year => 1776) 25
```

```
(Disk, Closed, Track => 5, Cylinder => 12) -- see 3.8.1 26
```

```
(Unit => Disk, Status => Closed, Cylinder => 9, Track => 1) 26
```

{AI95-00287-01} *Examples of component associations with several choices:* 27/2

```
(Value => 0, Succ|Pred => new Cell'(0, null, null)) -- see 3.10.1 28
```

```
-- The allocator is evaluated twice: Succ and Pred designate different cells 29
```

```
(Value => 0, Succ|Pred => <>) -- see 3.10.1 29.1/2
```

```
-- Succ and Pred will be set to null 29.2/2
```

Examples of record aggregates for tagged types (see 3.9 and 3.9.1): 30

```
Expression'(null record) 31
```

```
Literal'(Value => 0.0)
```

```
Painted_Point'(0.0, Pi/2.0, Paint => Red)
```

Extensions to Ada 83

Null record aggregates may now be specified, via "**(null record)**". However, this syntax is more useful for null record extensions in extension aggregates. 31.a

Wording Changes from Ada 83

Various AIs have been incorporated (AI83-00189, AI83-00244, and AI83-00309). In particular, Ada 83 did not explicitly disallow extra values in a record aggregate. Now we do. 31.b

Extensions to Ada 95

{AI95-00287-01} $\langle \rangle$ can be used in place of an expression in a `record_aggregate`, default initializing the component. 31.c/2

Wording Changes from Ada 95

- 31.d/2 {AI95-00287-01} Limited `record_aggregates` are allowed (since all kinds of aggregates can now be limited, see 4.3).

Incompatibilities With Ada 2005

- 31.e/3 {AI05-0220-1} **Correction:** Corrected wording so that the rule for discriminants governing `variant_parts` was not effectively circular. The change makes a few `aggregates` where a nonstatic discriminant governs an empty `variant_part` illegal. However, most Ada implementations already enforce some version of the new rule and already reject these aggregates. So it is unlikely that any incompatibility will be noticed in practice.

Extensions to Ada 2005

- 31.f/3 {AI05-0016-1} **Correction:** Fixed the wording so that `others => <>` can be used in place of `null record`. This is needed to avoid a generic contract issue for generic bodies: we do not want to have to assume the worst to disallow `others => <>` if the record type *might* be a null record.
- 31.g/3 {AI05-0199-1} **Correction:** We now allow multiple components with anonymous access types to be specified with a single component association. This is to be consistent with the capabilities of a named access type.

4.3.2 Extension Aggregates

- 1 [An `extension_aggregate` specifies a value for a type that is a record extension by specifying a value or subtype for an ancestor of the type, followed by associations for any components not determined by the `ancestor_part`.]

Language Design Principles

- 1.a The model underlying this syntax is that a record extension can also be viewed as a regular record type with an ancestor "prefix." The `record_component_association_list` corresponds to exactly what would be needed if there were no ancestor/prefix type. The `ancestor_part` determines the value of the ancestor/prefix.

Syntax

- ```
2 extension_aggregate ::=
3 (ancestor_part with record_component_association_list)
4 ancestor_part ::= expression | subtype_mark
```

*Name Resolution Rules*

- 4/2 {AI95-00287-01} The expected type for an `extension_aggregate` shall be a single type that is a record extension. If the `ancestor_part` is an `expression`, it is expected to be of any tagged type.
- 4.a **Reason:** We could have made the expected type  $T$ Class where  $T$  is the ultimate ancestor of the type of the aggregate, or we could have made it even more specific than that. However, if the overload resolution rules get too complicated, the implementation gets more difficult and it becomes harder to produce good error messages.
- 4.b/3 **Ramification:** {AI05-0005-1} This rule is additive with the rule given in 4.3. That means the 4.3 rule must be satisfied even though it is always syntactically possible to tell that something is an extension aggregate rather than another kind of aggregate. Specifically, that means that an extension aggregate is ambiguous if the context is overloaded on array and/or untagged record types, even though those are never legal contexts for an extension aggregate. Thus, this rule acts more like a Legality Rules than a Name Resolution Rules.

*Legality Rules*

- 5/3 {AI95-00306-01} {AI05-0115-1} If the `ancestor_part` is a `subtype_mark`, it shall denote a specific tagged subtype. If the `ancestor_part` is an `expression`, it shall not be dynamically tagged. The type of the `extension_aggregate` shall be a descendant of the type of the `ancestor_part` (the *ancestor* type), through one or more record extensions (and no private extensions). If the `ancestor_part` is a `subtype_mark`, the view of the ancestor type from which the type is descended (see 7.3.1) shall not have unknown discriminants.
- 5.a/2 **Reason:** {AI95-00306-01} The expression cannot be dynamically tagged to prevent implicit "truncation" of a dynamically-tagged value to the specific ancestor type. This is similar to the rules in 3.9.2.

{AI05-0067-1} {AI05-0244-1} If the type of the `ancestor_part` is limited and at least one component is needed in the `record_component_association_list`, then the `ancestor_part` shall not be: 5.1/3

- a call to a function with an unconstrained result subtype; nor 5.2/3
- a parenthesized or qualified expression whose operand would violate this rule; nor 5.3/3
- a `conditional_expression` having at least one *dependent\_expression* that would violate this rule. 5.4/3

**Reason:** {AI05-0067-1} {AI05-0244-1} This restriction simplifies implementation, because it ensures that either the caller or the callee knows the size to allocate for the aggregate. Without this restriction, information from both caller and callee would have to be combined to determine the appropriate size. 5.b/3

{AI05-0067-1} The (F(...)) with null record) case is exempt from this rule, because such extension aggregates are created internally for inherited functions returning null-extension types — we can't very well make those illegal. Moreover, we don't need the rule for null extensions, as the result can simply use the space returned by the function call. 5.c/3

#### Static Semantics

For the `record_component_association_list` of an `extension_aggregate`, the only components *needed* are those of the composite value defined by the aggregate that are not inherited from the type of the `ancestor_part`, plus any inherited discriminants if the `ancestor_part` is a `subtype_mark` that denotes an unconstrained subtype. 6

#### Dynamic Semantics

For the evaluation of an `extension_aggregate`, the `record_component_association_list` is evaluated. If the `ancestor_part` is an `expression`, it is also evaluated; if the `ancestor_part` is a `subtype_mark`, the components of the value of the aggregate not given by the `record_component_association_list` are initialized by default as for an object of the ancestor type. Any implicit initializations or evaluations are performed in an arbitrary order, except that the `expression` for a discriminant is evaluated prior to any other evaluation or initialization that depends on it. 7

{AI05-0282-1} If the type of the `ancestor_part` has discriminants and the `ancestor_part` is not a `subtype_mark` that denotes an unconstrained subtype, then a check is made that each discriminant determined by the `ancestor_part` has the value specified for a corresponding discriminant, if any, either in the `record_component_association_list`, or in the `derived_type_definition` for some ancestor of the type of the `extension_aggregate`. `Constraint_Error` is raised if this check fails. 8/3

**Ramification:** Corresponding and specified discriminants are defined in 3.7. The rules requiring static compatibility between new discriminants of a derived type and the parent discriminant(s) they constrain ensure that at most one check is required per discriminant of the ancestor expression. 8.a

{AI05-0282-1} The check needs to be made any time that the ancestor is constrained; the source of the discriminants or the constraints is irrelevant. 8.b/3

#### NOTES

8 If all components of the value of the `extension_aggregate` are determined by the `ancestor_part`, then the `record_component_association_list` is required to be simply **null record**. 9

9 If the `ancestor_part` is a `subtype_mark`, then its type can be abstract. If its type is controlled, then as the last step of evaluating the aggregate, the Initialize procedure of the ancestor type is called, unless the Initialize procedure is abstract (see 7.6). 10

#### Examples

*Examples of extension aggregates (for types defined in 3.9.1):* 11

```
Painted_Point'(Point with Red) 12
(Point'(P) with Paint => Black)
```

```
(Expression with Left => 1.2, Right => 3.4) 13
Addition'(Binop with null record)
-- presuming Binop is of type Binary_Operation
```

*Extensions to Ada 83*

13.a The extension aggregate syntax is new.

*Incompatibilities With Ada 95*

13.b/2 {AI95-00306-01} **Amendment Correction:** Eliminated implicit “truncation” of a dynamically tagged value when it is used as an ancestor expression. If an aggregate includes such an expression, it is illegal in Ada 2005. Such aggregates are thought to be rare; the problem can be fixed with a type conversion to the appropriate specific type if it occurs.

*Wording Changes from Ada 95*

13.c/2 {AI95-00287-01} Limited extension\_aggregates are allowed (since all kinds of aggregates can now be limited, see 4.3).

*Inconsistencies With Ada 2005*

13.d/3 {AI05-0282-1} **Correction:** An extension\_aggregate with an ancestor\_part whose discriminants are constrained and inherited might now raise Constraint\_Error if the aggregate's type is constrained, while it was OK in Ada 2005. In almost all cases, this will make no difference as the constraint will be checked by the immediately following use of the aggregate, but it is possible to compare such an aggregate for equality; in this case, no exception would be raised by Ada 2005, while Ada 2012 will raise Constraint\_Error. This should be very rare, and having the possibility means that the representation of the aggregate type has to be able to support unconstrained values of the type, even if the first subtype is constrained and no such objects can be created any other way.

*Incompatibilities With Ada 2005*

13.e/3 {AI05-0067-1} **Correction:** A limited unconstrained ancestor expression that is a function call is now illegal unless the extension part is null. Such aggregates were first introduced in Ada 2005 and are very complex to implement as they must be built-in-place with an unknown size; as such, it is unlikely that they are implemented correctly in existing compilers and thus not often used in existing code.

13.f/3 {AI05-0115-1} **Correction:** An ancestor\_part that is a subtype with unknown discriminants is now explicitly illegal. Such a subtype should not be used to declare an object, and the ancestor\_part acts like an object. The Ada 95 rules did not disallow such cases, so it is possible that code exists that uses such an ancestor, but this should be rare.

### 4.3.3 Array Aggregates

1 [In an array\_aggregate, a value is specified for each component of an array, either positionally or by its index.] For a positional\_array\_aggregate, the components are given in increasing-index order, with a final others, if any, representing any remaining components. For a named\_array\_aggregate, the components are identified by the values covered by the discrete\_choices.

*Language Design Principles*

1.a/1 The rules in this subclause are based on terms and rules for discrete\_choice\_lists defined in 3.8.1, “Variant Parts and Discrete Choices”. For example, the requirements that others come last and stand alone are found there.

*Syntax*

```

2 array_aggregate ::=
 positional_array_aggregate | named_array_aggregate
3/2 {AI95-00287-01} positional_array_aggregate ::=
 (expression, expression {, expression})
 | (expression {, expression}, others => expression)
 | (expression {, expression}, others => <>)
4 named_array_aggregate ::=
 (array_component_association {, array_component_association})
5/2 {AI95-00287-01} array_component_association ::=
 discrete_choice_list => expression
 | discrete_choice_list => <>

```

An *n*-dimensional `array_aggregate` is one that is written as *n* levels of nested `array_aggregates` (or at the bottom level, equivalent `string_literals`). For the multidimensional case ( $n \geq 2$ ) the `array_aggregates` (or equivalent `string_literals`) at the  $n-1$  lower levels are called *subaggregates* of the enclosing *n*-dimensional `array_aggregate`. The expressions of the bottom level subaggregates (or of the `array_aggregate` itself if one-dimensional) are called the *array component expressions* of the enclosing *n*-dimensional `array_aggregate`. 6

**Ramification:** Subaggregates do not have a type. They correspond to part of an array. For example, with a matrix, a subaggregate would correspond to a single row of the matrix. The definition of "n-dimensional" `array_aggregate` applies to subaggregates as well as aggregates that have a type. 6.a

**To be honest:** An *others choice* is the reserved word **others** as it appears in a `positional_array_aggregate` or as the `discrete_choice` of the `discrete_choice_list` in an `array_component_association`. 6.b

#### Name Resolution Rules

{AI95-00287-01} The expected type for an `array_aggregate` (that is not a subaggregate) shall be a single array type. The component type of this array type is the expected type for each array component expression of the `array_aggregate`. 7/2

**Ramification:** {AI95-00287-01} We already require a single array or record type or record extension for an aggregate. The above rule requiring a single array type (and similar ones for record and extension aggregates) resolves which kind of aggregate you have. 7.a/2

The expected type for each `discrete_choice` in any `discrete_choice_list` of a `named_array_aggregate` is the type of the *corresponding index*; the corresponding index for an `array_aggregate` that is not a subaggregate is the first index of its type; for an ( $n-m$ )-dimensional subaggregate within an `array_aggregate` of an *n*-dimensional type, the corresponding index is the index in position  $m+1$ . 8

#### Legality Rules

An `array_aggregate` of an *n*-dimensional array type shall be written as an *n*-dimensional `array_aggregate`. 9

**Ramification:** In an *m*-dimensional `array_aggregate` [(including a subaggregate)], where  $m \geq 2$ , each of the expressions has to be an ( $m-1$ )-dimensional subaggregate. 9.a

An **others choice** is allowed for an `array_aggregate` only if an *applicable index constraint* applies to the `array_aggregate`. [An applicable index constraint is a constraint provided by certain contexts where an `array_aggregate` is permitted that can be used to determine the bounds of the array value specified by the aggregate.] Each of the following contexts (and none other) defines an applicable index constraint: 10

- {AI95-00318-02} For an `explicit_actual_parameter`, an `explicit_generic_actual_parameter`, the expression of a return statement, the initialization expression in an `object_declaration`, or a `default_expression` [(for a parameter or a component)], when the nominal subtype of the corresponding formal parameter, generic formal parameter, function return object, object, or component is a constrained array subtype, the applicable index constraint is the constraint of the subtype; 11/2
- For the expression of an `assignment_statement` where the name denotes an array variable, the applicable index constraint is the constraint of the array variable; 12

**Reason:** This case is broken out because the constraint comes from the actual subtype of the variable (which is always constrained) rather than its nominal subtype (which might be unconstrained). 12.a

- For the operand of a `qualified_expression` whose `subtype_mark` denotes a constrained array subtype, the applicable index constraint is the constraint of the subtype; 13
- For a component expression in an `aggregate`, if the component's nominal subtype is a constrained array subtype, the applicable index constraint is the constraint of the subtype; 14

**Discussion:** Here, the `array_aggregate` with **others** is being used within a larger aggregate. 14.a

- 15/3 • *{AI05-0147-1}* For a parenthesized expression, the applicable index constraint is that, if any, defined for the expression;
- 15.a **Discussion:** RM83 omitted this case, presumably as an oversight. We want to minimize situations where an expression becomes illegal if parenthesized.
- 15.1/3 • *{AI05-0147-1}* For a conditional\_expression, the applicable index constraint for each dependent\_expression is that, if any, defined for the conditional\_expression.
- 16 The applicable index constraint *applies* to an array\_aggregate that appears in such a context, as well as to any subaggregates thereof. In the case of an explicit\_actual\_parameter (or default\_expression) for a call on a generic formal subprogram, no applicable index constraint is defined.
- 16.a **Reason:** This avoids generic contract model problems, because only mode conformance is required when matching actual subprograms with generic formal subprograms.
- 17/3 *{AI05-0153-3}* The discrete\_choice\_list of an array\_component\_association is allowed to have a discrete\_choice that is a nonstatic choice\_expression or that is a subtype\_indication or range that defines a nonstatic or null range, only if it is the single discrete\_choice of its discrete\_choice\_list, and there is only one array\_component\_association in the array\_aggregate.
- 17.a **Discussion:** We now allow a nonstatic **others** choice even if there are other array component expressions as well.
- 18/3 *{AI05-0262-1}* In a named\_array\_aggregate where all discrete\_choices are static, no two discrete\_choices are allowed to cover the same value (see 3.8.1); if there is no **others** choice, the discrete\_choices taken together shall exactly cover a contiguous sequence of values of the corresponding index type.
- 18.a **Ramification:** This implies that each component must be specified exactly once. See AI83-309.
- 18.b/3 **Reason:** *{AI05-0262-1}* This has to apply even if there is only one static discrete\_choice; a single choice has to represent a contiguous range (a subtype\_mark with a static predicate might represent a discontinuous set of values). If the (single) choice is a dynamic subtype, we don't need to make this check as no predicates are allowed (see 3.2.4) and thus the range has to be contiguous.
- 19 A bottom level subaggregate of a multidimensional array\_aggregate of a given array type is allowed to be a string\_literal only if the component type of the array type is a character type; each character of such a string\_literal shall correspond to a defining\_character\_literal of the component type.

*Static Semantics*

- 20 A subaggregate that is a string\_literal is equivalent to one that is a positional\_array\_aggregate of the same length, with each expression being the character\_literal for the corresponding character of the string\_literal.

*Dynamic Semantics*

- 21 The evaluation of an array\_aggregate of a given array type proceeds in two steps:
- 22 1. Any discrete\_choices of this aggregate and of its subaggregates are evaluated in an arbitrary order, and converted to the corresponding index type;
- 23 2. The array component expressions of the aggregate are evaluated in an arbitrary order and their values are converted to the component subtype of the array type; an array component expression is evaluated once for each associated component.
- 23.a **Ramification:** Subaggregates are not separately evaluated. The conversion of the value of the component expressions to the component subtype might raise Constraint\_Error.
- 23.b/3 *{AI05-0005-1}* We don't need to say that  $\diamond$  is evaluated once for each component, as  $\diamond$  means that each component is *initialized by default*. That means that the actions defined for default initialization are applied to each component individually. Initializing one component by default and copying that to the others would be an incorrect implementation in general (although it might be OK if the default initialization is known to be constant).

{AI95-00287-01} Each `expression` in an `array_component_association` defines the value for the associated component(s). For an `array_component_association` with  $\diamond$ , the associated component(s) are initialized by default as for a stand-alone object of the component subtype (see 3.3.1). 23.1/2

The bounds of the index range of an `array_aggregate` [(including a subaggregate)] are determined as follows: 24

- For an `array_aggregate` with an **others** choice, the bounds are those of the corresponding index range from the applicable index constraint; 25
- For a `positional_array_aggregate` [(or equivalent `string_literal`)] without an **others** choice, the lower bound is that of the corresponding index range in the applicable index constraint, if defined, or that of the corresponding index subtype, if not; in either case, the upper bound is determined from the lower bound and the number of `expressions` [(or the length of the `string_literal`)]; 26
- For a `named_array_aggregate` without an **others** choice, the bounds are determined by the smallest and largest index values covered by any `discrete_choice_list`. 27

**Reason:** We don't need to say that each index value has to be covered exactly once, since that is a ramification of the general rule on aggregates that each component's value has to be specified exactly once. 27.a

For an `array_aggregate`, a check is made that the index range defined by its bounds is compatible with the corresponding index subtype. 28

**Discussion:** In RM83, this was phrased more explicitly, but once we define "compatibility" between a range and a subtype, it seems to make sense to take advantage of that definition. 28.a

**Ramification:** The definition of compatibility handles the special case of a null range, which is always compatible with a subtype. See AI83-00313. 28.b

{AI05-0037-1} For an `array_aggregate` with an **others** choice, a check is made that no `expression` or  $\diamond$  is specified for an index value outside the bounds determined by the applicable index constraint. 29/3

**Discussion:** RM83 omitted this case, apparently through an oversight. AI83-00309 defines this as a dynamic check, even though other Ada 83 rules ensured that this check could be performed statically. We now allow an **others** choice to be dynamic, even if it is not the only choice, so this check now needs to be dynamic, in some cases. Also, within a generic unit, this would be a nonstatic check in some cases. 29.a

For a multidimensional `array_aggregate`, a check is made that all subaggregates that correspond to the same index have the same bounds. 30

**Ramification:** No array bounds "sliding" is performed on subaggregates. 30.a

**Reason:** If sliding were performed, it would not be obvious which subaggregate would determine the bounds of the corresponding index. 30.b

The exception `Constraint_Error` is raised if any of the above checks fail. 31

#### NOTES

10 {AI05-0004-1} In an `array_aggregate`, positional notation may only be used with two or more `expressions`; a single `expression` in parentheses is interpreted as a parenthesized `expression`. A `named_array_aggregate`, such as `(1 => X)`, may be used to specify an array with a single component. 32/3

#### Examples

*Examples of array aggregates with positional associations:* 33

```
(7, 9, 5, 1, 3, 2, 4, 8, 6, 0) 34
Table'(5, 8, 4, 1, others => 0) -- see 3.6
```

*Examples of array aggregates with named associations:* 35

```
(1 .. 5 => (1 .. 8 => 0.0)) -- two-dimensional 36
(1 .. N => new Cell) -- N new cells, in particular for N = 0
```

```

37 Table'(2 | 4 | 10 => 1, others => 0)
 Schedule'(Mon .. Fri => True, others => False) -- see 3.6
 Schedule'(Wed | Sun => False, others => True)
 Vector'(1 => 2.5) -- single-component vector

```

38 *Examples of two-dimensional array aggregates:*

```

39 -- Three aggregates for the same value of subtype Matrix(1..2,1..3) (see 3.6):
40 ((1.1, 1.2, 1.3), (2.1, 2.2, 2.3))
 (1 => (1.1, 1.2, 1.3), 2 => (2.1, 2.2, 2.3))
 (1 => (1 => 1.1, 2 => 1.2, 3 => 1.3), 2 => (1 => 2.1, 2 => 2.2, 3 => 2.3))

```

41 *Examples of aggregates as initial values:*

```

42 A : Table := (7, 9, 5, 1, 3, 2, 4, 8, 6, 0); -- A(1)=7, A(10)=0
 B : Table := (2 | 4 | 10 => 1, others => 0); -- B(1)=0, B(10)=1
 C : constant Matrix := (1 .. 5 => (1 .. 8 => 0.0)); -- C'Last(1)=5, C'Last(2)=8
43 D : Bit_Vector(M .. N) := (M .. N => True); -- see 3.6
 E : Bit_Vector(M .. N) := (others => True);
 F : String(1 .. 1) := (1 => 'F'); -- a one component aggregate: same as "F"

```

44/2 {AI95-00433-01} *Example of an array aggregate with defaulted others choice and with an applicable index constraint provided by an enclosing record aggregate:*

```

45/2 Buffer'(Size => 50, Pos => 1, Value => String('x', others => <>)) -- see 3.7

```

#### *Incompatibilities With Ada 83*

45.a.1/1 In Ada 95, no applicable index constraint is defined for a parameter in a call to a generic formal subprogram; thus, some aggregates that are legal in Ada 83 are illegal in Ada 95. For example:

```

45.a.2/1 subtype S3 is String (1 .. 3);
 ...
 generic
 with function F (The_S3 : in S3) return Integer;
 package Gp is
 I : constant Integer := F ((1 => '!', others => '?'));
 -- The aggregate is legal in Ada 83, illegal in Ada 95.
 end Gp;

```

45.a.3/1 This change eliminates generic contract model problems.

#### *Extensions to Ada 83*

45.a We now allow "named with others" aggregates in all contexts where there is an applicable index constraint, effectively eliminating what was RM83-4.3.2(6). Sliding never occurs on an aggregate with others, because its bounds come from the applicable index constraint, and therefore already match the bounds of the target.

45.b The legality of an **others** choice is no longer affected by the staticness of the applicable index constraint. This substantially simplifies several rules, while being slightly more flexible for the user. It obviates the rulings of AI83-00244 and AI83-00310, while taking advantage of the dynamic nature of the "extra values" check required by AI83-00309.

45.c Named array aggregates are permitted even if the index type is descended from a formal scalar type. See 4.9 and AI83-00190.

#### *Wording Changes from Ada 83*

45.d We now separate named and positional array aggregate syntax, since, unlike other aggregates, named and positional associations cannot be mixed in array aggregates (except that an **others** choice is allowed in a positional array aggregate).

45.e We have also reorganized the presentation to handle multidimensional and one-dimensional aggregates more uniformly, and to incorporate the rulings of AI83-00019, AI83-00309, etc.

#### *Extensions to Ada 95*

45.f/2 {AI95-00287-01} <> can be used in place of an expression in an array\_aggregate, default-initializing the component.

*Wording Changes from Ada 95*

{AI95-00287-01} Limited `array_aggregates` are allowed (since all kinds of aggregates can now be limited, see 4.3). 45.g/2

{AI95-00318-02} Fixed aggregates to use the subtype of the return object of a function, rather than the result subtype, because they can be different for an `extended_return_statement`, and we want to use the subtype that's explicitly in the code at the point of the expression. 45.h/2

*Inconsistencies With Ada 2005*

{AI05-0037-1} **Correction:** Fixed so the check for components outside of the array applies to both expressions and `<>`s. As `<>` was a new feature in Ada 2005, there should be little existing code that depends on a `<>` component that is specified outside of the array (and that is nonsense anyway, that a compiler is likely to detect even without an explicit language rule disallowing it). 45.i/3

*Wording Changes from Ada 2005*

{AI05-0147-1} Added a definition of the applicable index constraint for `conditional_expressions` (which are new). 45.j/3

## 4.4 Expressions

{AI05-0147-1} {AI05-0158-1} {AI05-0176-1} An *expression* is a formula that defines the computation or retrieval of a value. In this International Standard, the term “expression” refers to a construct of the syntactic category `expression` or of any of the following categories: `choice_expression`, `choice_relation`, `relation`, `simple_expression`, `term`, `factor`, `primary`, `conditional_expression`, `quantified_expression`. 1/3

*Syntax*

```

expression ::=
 relation {and relation} | relation {and then relation}
 | relation {or relation} | relation {or else relation}
 | relation {xor relation}
 2

{AI05-0158-1} choice_expression ::=
 choice_relation {and choice_relation}
 | choice_relation {or choice_relation}
 | choice_relation {xor choice_relation}
 | choice_relation {and then choice_relation}
 | choice_relation {or else choice_relation}
 2.1/3

{AI05-0158-1} choice_relation ::=
 simple_expression [relational_operator simple_expression]
 2.2/3

{AI05-0158-1} relation ::=
 simple_expression [relational_operator simple_expression]
 | simple_expression [not] in membership_choice_list
 3/3

{AI05-0158-1} membership_choice_list ::= membership_choice { | membership_choice }
 3.1/3

{AI05-0158-1} membership_choice ::= choice_expression | range | subtype_mark
 3.2/3

simple_expression ::= [unary_adding_operator] term {binary_adding_operator term}
 4

term ::= factor {multiplying_operator factor}
 5

factor ::= primary [** primary] | abs primary | not primary
 6

{AI05-0003-1} {AI05-0147-1} {AI05-0176-1} primary ::=
 numeric_literal | null | string_literal | aggregate
 | name | allocator | (expression)
 | (conditional_expression) | (quantified_expression)
 7/3

```

*Name Resolution Rules*

8 A name used as a primary shall resolve to denote an object or a value.

8.a **Discussion:** This replaces RM83-4.4(3). We don't need to mention named numbers explicitly, because the name of a named number denotes a value. We don't need to mention attributes explicitly, because attributes now denote (rather than yield) values in general. Also, the new wording allows attributes that denote objects, which should always have been allowed (in case the implementation chose to have such a thing).

8.b **Reason:** It might seem odd that this is an overload resolution rule, but it is relevant during overload resolution. For example, it helps ensure that a primary that consists of only the identifier of a parameterless function is interpreted as a `function_call` rather than directly as a `direct_name`.

*Static Semantics*

9 Each expression has a type; it specifies the computation or retrieval of a value of that type.

*Dynamic Semantics*

10 The value of a primary that is a name denoting an object is the value of the object.

*Implementation Permissions*

11 For the evaluation of a primary that is a name denoting an object of an unconstrained numeric subtype, if the value of the object is outside the base range of its type, the implementation may either raise `Constraint_Error` or return the value of the object.

11.a/3 **Ramification:** *{AI05-0299-1}* This means that if extra-range intermediates are used to hold the value of an object of an unconstrained numeric subtype, a `Constraint_Error` can be raised on a read of the object, rather than only on an assignment to it. Similarly, it means that computing the value of an object of such a subtype can be deferred until the first read of the object (presuming no side effects other than failing an `Overflow_Check` are possible). This permission is over and above that provided by subclause 11.6, since this allows the `Constraint_Error` to move to a different handler.

11.b **Reason:** This permission is intended to allow extra-range registers to be used efficiently to hold parameters and local variables, even if they might need to be transferred into smaller registers for performing certain predefined operations.

11.c **Discussion:** There is no need to mention other kinds of primaries, since any `Constraint_Error` to be raised can be “charged” to the evaluation of the particular kind of primary.

*Examples*

12 *Examples of primaries:*

```
13 4.0 -- real literal
 Pi -- named number
 (1 .. 10 => 0) -- array aggregate
 Sum -- variable
 Integer'Last -- attribute
 Sine(X) -- function call
 Color'(Blue) -- qualified expression
 Real(M*N) -- conversion
 (Line_Count + 10) -- parenthesized expression
```

14 *Examples of expressions:*

```
15/2 {AI95-00433-01} Volume -- primary
 not Destroyed -- factor
 2*Line_Count -- term
 -4.0 -- simple expression
 -4.0 + A -- simple expression
 B**2 - 4.0*A*C -- simple expression
 R*Sin(θ)*Cos(φ) -- simple expression
 Password(1 .. 3) = "Bwv" -- relation
 Count in Small_Int -- relation
 Count not in Small_Int -- relation
 Index = 0 or Item_Hit -- expression
 (Cold and Sunny) or Warm -- expression (parentheses are required)
 A** (B**C) -- expression (parentheses are required)
```

*Extensions to Ada 83*

In Ada 83, **out** parameters and their nondiscriminant subcomponents are not allowed as **primaries**. These restrictions are eliminated in Ada 95. 15.a

In various contexts throughout the language where Ada 83 syntax rules had **simple\_expression**, the corresponding Ada 95 syntax rule has **expression** instead. This reflects the inclusion of modular integer types, which makes the logical operators "**and**", "**or**", and "**xor**" more useful in expressions of an integer type. Requiring parentheses to use these operators in such contexts seemed unnecessary and potentially confusing. Note that the bounds of a **range** still have to be specified by **simple\_expressions**, since otherwise **expressions** involving membership tests might be ambiguous. Essentially, the operation **".."** is of higher precedence than the logical operators, and hence uses of logical operators still have to be parenthesized when used in a bound of a **range**. 15.b

*Wording Changes from Ada 2005*

{AI05-0003-1} Moved **qualified\_expression** from **primary** to **name** (see 4.1). This allows the use of **qualified\_expressions** in more places. 15.c/3

{AI05-0147-1} {AI05-0176-1} Added **conditional\_expression** and **quantified\_expression** to **primary**. 15.d/3

{AI05-0158-1} Expanded membership test syntax (see 4.5.2). 15.e/3

## 4.5 Operators and Expression Evaluation

[ The language defines the following six categories of operators (given in order of increasing precedence). The corresponding **operator\_symbols**, and only those, can be used as **designators** in declarations of functions for user-defined operators. See 6.6, "Overloading of Operators".] 1

*Syntax*

|                                 |                                     |   |
|---------------------------------|-------------------------------------|---|
| logical_operator ::=            | <b>and</b>   <b>or</b>   <b>xor</b> | 2 |
| relational_operator ::=         | =   /=   <   <=   >   >=            | 3 |
| binary_adding_operator ::=      | +   -   &                           | 4 |
| unary_adding_operator ::=       | +   -                               | 5 |
| multiplying_operator ::=        | *   /   <b>mod</b>   <b>rem</b>     | 6 |
| highest_precedence_operator ::= | **   <b>abs</b>   <b>not</b>        | 7 |

**Discussion:** Some of the above syntactic categories are not used in other syntax rules. They are just used for classification. The others are used for both classification and parsing. 7.a

*Static Semantics*

For a sequence of operators of the same precedence level, the operators are associated with their operands in textual order from left to right. Parentheses can be used to impose specific associations. 8

**Discussion:** The left-associativity is not directly inherent in the grammar of 4.4, though in 1.1.4 the definition of the metasympols **{}** implies left associativity. So this could be seen as redundant, depending on how literally one interprets the definition of the **{}** metasympols. 8.a

See the Implementation Permissions below regarding flexibility in reassociating operators of the same precedence. 8.b

For each form of type definition, certain of the above operators are *predefined*; that is, they are implicitly declared immediately after the type definition. For each such implicit operator declaration, the parameters are called Left and Right for *binary* operators; the single parameter is called Right for *unary* operators. [An expression of the form X op Y, where op is a binary operator, is equivalent to a **function\_call** of the form "op"(X, Y). An expression of the form op Y, where op is a unary operator, is equivalent to a **function\_call** of the form "op"(Y). The predefined operators and their effects are described in subclauses 4.5.1 through 4.5.6.] 9

*Dynamic Semantics*

10 [ The predefined operations on integer types either yield the mathematically correct result or raise the exception `Constraint_Error`. For implementations that support the Numerics Annex, the predefined operations on real types yield results whose accuracy is defined in Annex G, or raise the exception `Constraint_Error`. ]

10.a **To be honest:** Predefined operations on real types can “silently” give wrong results when the `Machine_Overflows` attribute is false, and the computation overflows.

*Implementation Requirements*

11 The implementation of a predefined operator that delivers a result of an integer or fixed point type may raise `Constraint_Error` only if the result is outside the base range of the result type.

12 The implementation of a predefined operator that delivers a result of a floating point type may raise `Constraint_Error` only if the result is outside the safe range of the result type.

12.a **To be honest:** An exception is made for exponentiation by a negative exponent in 4.5.6.

*Implementation Permissions*

13 For a sequence of predefined operators of the same precedence level (and in the absence of parentheses imposing a specific association), an implementation may impose any association of the operators with operands so long as the result produced is an allowed result for the left-to-right association, but ignoring the potential for failure of language-defined checks in either the left-to-right or chosen order of association.

13.a **Discussion:** Note that the permission to reassociate the operands in any way subject to producing a result allowed for the left-to-right association is not much help for most floating point operators, since reassociation may introduce significantly different round-off errors, delivering a result that is outside the model interval for the left-to-right association. Similar problems arise for division with integer or fixed point operands.

13.b Note that this permission does not apply to user-defined operators.

## NOTES

14 11 The two operands of an expression of the form `X op Y`, where `op` is a binary operator, are evaluated in an arbitrary order, as for any `function_call` (see 6.4).

*Examples*

15 *Examples of precedence:*

16 `not Sunny or Warm` -- same as *(not Sunny) or Warm*  
`X > 4.0 and Y > 0.0` -- same as *(X > 4.0) and (Y > 0.0)*

17 `-4.0 * A ** 2` -- same as *-(4.0 \* (A \*\* 2))*  
`abs (1 + A) + B` -- same as *(abs (1 + A)) + B*  
`Y ** (-3)` -- *parentheses are necessary*  
`A / B * C` -- same as *(A/B)\*C*  
`A + (B + C)` -- *evaluate B + C before adding it to A*

*Wording Changes from Ada 83*

17.a We don't give a detailed definition of precedence, since it is all implicit in the syntax rules anyway.

17.b The permission to reassociate is moved here from RM83-11.6(5), so it is closer to the rules defining operator association.

## 4.5.1 Logical Operators and Short-circuit Control Forms

*Name Resolution Rules*

1 An expression consisting of two relations connected by **and then** or **or else** (a *short-circuit control form*) shall resolve to be of some boolean type; the expected type for both relations is that same boolean type.

**Reason:** This rule is written this way so that overload resolution treats the two operands symmetrically; the resolution of overloading present in either one can benefit from the resolution of the other. Furthermore, the type expected by context can help. 1.a

*Static Semantics*

The following logical operators are predefined for every boolean type *T*, for every modular type *T*, and for every one-dimensional array type *T* whose component type is a boolean type: 2

```
function "and" (Left, Right : T) return T
function "or" (Left, Right : T) return T
function "xor" (Left, Right : T) return T
```

3

*This paragraph was deleted. {AI95-00145-01}* 3.a/2

**Ramification:** {AI95-00145-01} For these operators, we are talking about the type without any (interesting) subtype, and not some subtype with a constraint or exclusion. Since it's possible that there is no name for the “uninteresting” subtype, we denote the type with an italicized *T*. This applies to the italicized *T* in many other predefined operators and attributes as well. 3.b/2

{AI95-00145-01} In many cases, there is a subtype with the correct properties available. The italicized *T* means: 3.c/2

- *T*Base, for scalars; 3.d/2
- the first subtype of *T*, for tagged types; 3.e/2
- a subtype of the type *T* without any constraint or null exclusion, in other cases. 3.f/2

Note that “without a constraint” is not the same as unconstrained. For instance, a record type with no discriminant part is considered constrained; no subtype of it has a constraint, but the subtype is still constrained. 3.g/2

Thus, the last case often is the same as the first subtype of *T*, but that isn't the case for constrained array types (where the correct subtype is unconstrained) and for access types with a null\_exclusion (where the correct subtype does not exclude null). 3.h/2

This italicized *T* is used for defining operators and attributes of the language. The meaning is intended to be as described here. 3.i/2

For boolean types, the predefined logical operators **and**, **or**, and **xor** perform the conventional operations of conjunction, inclusive disjunction, and exclusive disjunction, respectively. 4

For modular types, the predefined logical operators are defined on a bit-by-bit basis, using the binary representation of the value of the operands to yield a binary representation for the result, where zero represents False and one represents True. If this result is outside the base range of the type, a final subtraction by the modulus is performed to bring the result into the base range of the type. 5

The logical operators on arrays are performed on a component-by-component basis on matching components (as for equality — see 4.5.2), using the predefined logical operator for the component type. The bounds of the resulting array are those of the left operand. 6

*Dynamic Semantics*

The short-circuit control forms **and then** and **or else** deliver the same result as the corresponding predefined **and** and **or** operators for boolean types, except that the left operand is always evaluated first, and the right operand is not evaluated if the value of the left operand determines the result. 7

For the logical operators on arrays, a check is made that for each component of the left operand there is a matching component of the right operand, and vice versa. Also, a check is made that each component of the result belongs to the component subtype. The exception Constraint\_Error is raised if either of the above checks fails. 8

**Discussion:** The check against the component subtype is per AI83-00535. 8.a

NOTES

12 The conventional meaning of the logical operators is given by the following truth table: 9

| A    | B    | (A and B) | (A or B) | (A xor B) | 10 |
|------|------|-----------|----------|-----------|----|
| True | True | True      | True     | False     |    |

|       |       |       |       |       |
|-------|-------|-------|-------|-------|
| True  | False | False | True  | True  |
| False | True  | False | True  | True  |
| False | False | False | False | False |

*Examples*

11 *Examples of logical operators:*

12     Sunny **or** Warm  
 12     Filter(1 .. 10) **and** Filter(15 .. 24)   -- see 3.6.1

13 *Examples of short-circuit control forms:*

14     Next\_Car.Owner /= **null and then** Next\_Car.Owner.Age > 25   -- see 3.10.1  
 14     N = 0 **or else** A(N) = Hit\_Value

## 4.5.2 Relational Operators and Membership Tests

1 [ The *equality operators* = (equals) and /= (not equals) are predefined for nonlimited types. The other *relational operators* are the *ordering operators* < (less than), <= (less than or equal), > (greater than), and >= (greater than or equal). The ordering operators are predefined for scalar types, and for *discrete array types*, that is, one-dimensional array types whose components are of a discrete type.

1.a     **Ramification:** The equality operators are not defined for *every* nonlimited type — see below for the exact rule.

2/3 {AI05-0262-1} {AI05-0269-1} A *membership test*, using **in** or **not in**, determines whether or not a value belongs to any given subtype or range, is equal to any given value, has a tag that identifies a type that is covered by a given type, or is convertible to and has an accessibility level appropriate for a given access type. Membership tests are allowed for all types.]

*Name Resolution Rules*

3/3 {AI95-00251-01} {AI05-0158-1} The *tested type* of a membership test is determined by the *membership\_choices* of the *membership\_choice\_list*. Either all *membership\_choices* of the *membership\_choice\_list* shall resolve to the same type, which is the tested type; or each *membership\_choice* shall be of an elementary type, and the tested type shall be covered by each of these elementary types.

3.1/3 {AI05-0158-1} If the tested type is tagged, then the *simple\_expression* shall resolve to be of a type that is convertible (see 4.6) to the tested type; if untagged, the expected type for the *simple\_expression* is the tested type. The expected type of a *choice\_expression* in a *membership\_choice*, and of a *simple\_expression* of a range in a *membership\_choice*, is the tested type of the membership operation.

3.a/2     **Reason:** {AI95-00230-01} The part of the rule for untagged types is stated in a way that ensures that operands like a string literal are still legal as operands of a membership test.

3.b/2     {AI95-00251-01} The significance of “is convertible to” is that we allow the *simple\_expression* to be of any class-wide type that could be converted to the tested type, not just the one rooted at the tested type. This includes any class-wide type that covers the tested type, along with class-wide interfaces in some cases.

3.c/3     {AI05-0158-1} The special rule for determining the tested type for elementary types is to allow numeric literals in *membership\_choice\_lists*. Without the rule, A **in** B | 1 would be illegal as B and 1 would have different types (the literal having type *universal integer*).

*Legality Rules*

4 For a membership test, if the *simple\_expression* is of a tagged class-wide type, then the tested type shall be (visibly) tagged.

4.a     **Ramification:** Untagged types covered by the tagged class-wide type are not permitted. Such types can exist if they are descendants of a private type whose full type is tagged. This rule is intended to avoid confusion since such derivatives don't have their “own” tag, and hence are indistinguishable from one another at run time once converted to a covering class-wide type.

{AI05-0158-1} If a membership test includes one or more `choice_expressions` and the tested type of the membership test is limited, then the tested type of the membership test shall have a visible primitive equality operator. 4.1/3

**Reason:** {AI05-0158-1} A visible equality operator is required in order to avoid breaking privacy; that is, we don't want to depend on a hidden equality operator. 4.b/3

#### Static Semantics

The result type of a membership test is the predefined type `Boolean`. 5

The equality operators are predefined for every specific type  $T$  that is not limited, and not an anonymous access type, with the following specifications: 6

```
function "=" (Left, Right : T) return Boolean 7
function "/=" (Left, Right : T) return Boolean
```

{AI95-00230-01} The following additional equality operators for the `universal_access` type are declared in package `Standard` for use with anonymous access types: 7.1/2

```
function "=" (Left, Right : universal_access) return Boolean 7.2/2
function "/=" (Left, Right : universal_access) return Boolean
```

The ordering operators are predefined for every specific scalar type  $T$ , and for every discrete array type  $T$ , with the following specifications: 8

```
function "<" (Left, Right : T) return Boolean 9
function "<=" (Left, Right : T) return Boolean
function ">" (Left, Right : T) return Boolean
function ">=" (Left, Right : T) return Boolean
```

#### Name Resolution Rules

{AI95-00230-01} {AI95-00420-01} At least one of the operands of an equality operator for `universal_access` shall be of a specific anonymous access type. Unless the predefined equality operator is identified using an expanded name with `prefix` denoting the package `Standard`, neither operand shall be of an access-to-object type whose designated type is  $D$  or  $D$ 'Class, where  $D$  has a user-defined primitive equality operator such that: 9.1/2

- its result type is `Boolean`; 9.2/2
- {AI05-0020-1} it is declared immediately within the same declaration list as  $D$  or any partial or incomplete view of  $D$ ; and 9.3/3
- at least one of its operands is an access parameter with designated type  $D$ . 9.4/2

**Reason:** The first sentence prevents compatibility problems by ensuring that these operators are not used for named access types. Also, universal access types do not count for the purposes of this rule. Otherwise, equality expressions like `(X = null)` would be ambiguous for normal access types. 9.a/2

The rest of the rule makes it possible to call (including a dispatching call) user-defined "=" operators for anonymous access-to-object types (they'd be hidden otherwise), and to write user-defined "=" operations for anonymous access types (by making it possible to see the universal operator using the `Standard` prefix). 9.b/2

**Ramification:** We don't need a similar rule for anonymous access-to-subprogram types because they can't be primitive for any type. Note that any nonprimitive user-defined equality operators still are hidden by the universal operators; they'll have to be called with a package prefix, but they are likely to be very uncommon. 9.c/2

#### Legality Rules

{AI95-00230-01} At least one of the operands of the equality operators for `universal_access` shall be of type `universal_access`, or both shall be of access-to-object types, or both shall be of access-to-subprogram types. Further: 9.5/2

- 9.6/2 • When both are of access-to-object types, the designated types shall be the same or one shall cover the other, and if the designated types are elementary or array types, then the designated subtypes shall statically match;
- 9.7/2 • When both are of access-to-subprogram types, the designated profiles shall be subtype conformant.
- 9.d/2 **Reason:** We don't want to allow completely arbitrary comparisons, as we don't want to insist that all access types are represented in ways that are convertible to one another. For instance, a compiler could use completely separate address spaces or incompatible representations. Instead, we allow compares if there exists an access parameter to which both operands could be converted. Since the user could write such a subprogram, and any reasonable meaning for "=" would allow using it in such a subprogram, this doesn't impose any further restrictions on Ada implementations.
- 9.8/3 {AI05-0123-1} If the profile of an explicitly declared primitive equality operator of an untagged record type is type conformant with that of the corresponding predefined equality operator, the declaration shall occur before the type is frozen. In addition, if the untagged record type has a nonlimited partial view, then the declaration shall occur in the visible part of the enclosing package. In addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit.

*Dynamic Semantics*

- 10 For discrete types, the predefined relational operators are defined in terms of corresponding mathematical operations on the position numbers of the values of the operands.
- 11 For real types, the predefined relational operators are defined in terms of the corresponding mathematical operations on the values of the operands, subject to the accuracy of the type.
- 11.a **Ramification:** For floating point types, the results of comparing *nearly* equal values depends on the accuracy of the implementation (see G.2.1, “Model of Floating Point Arithmetic” for implementations that support the Numerics Annex).
- 11.b **Implementation Note:** On a machine with signed zeros, if the generated code generates both plus zero and minus zero, plus and minus zero must be equal by the predefined equality operators.
- 12 Two access-to-object values are equal if they designate the same object, or if both are equal to the null value of the access type.
- 13 Two access-to-subprogram values are equal if they are the result of the same evaluation of an Access `attribute_reference`, or if both are equal to the null value of the access type. Two access-to-subprogram values are unequal if they designate different subprograms. [It is unspecified whether two access values that designate the same subprogram but are the result of distinct evaluations of Access `attribute_references` are equal or unequal.]
- 13.a **Reason:** This allows each Access `attribute_reference` for a subprogram to designate a distinct “wrapper” subprogram if necessary to support an indirect call.
- 14/3 {AI05-0123-1} For a type extension, predefined equality is defined in terms of the primitive [(possibly user-defined)] equals operator for the parent type and for any components that have a record type in the extension part, and predefined equality for any other components not inherited from the parent type.
- 14.a **Ramification:** Two values of a type extension are not equal if there is a `variant_part` in the extension part and the two values have different `variants` present. This is a ramification of the requirement that a discriminant governing such a `variant_part` has to be a “new” discriminant, and so has to be equal in the two values for the values to be equal. Note that `variant_parts` in the parent part need not match if the primitive equals operator for the parent type considers them equal.
- 14.b/2 {AI95-00349-01} The full type extension's operation is used for a private extension. This follows as only full types have parent types; the type specified in a private extension is an ancestor, but not necessarily the parent type. For instance, in:

```

with Pak1;
package Pak2 is
 type Typ3 is new Pak1.Typ1 with private;
private
 type Typ3 is new Pak1.Typ2 with null record;
end Pak2;

```

14.c/2

the parent type is Pak1.Typ2, not Pak1.Typ1, and the equality operator of Pak1.Typ2 is used to create predefined equality for Typ3.

14.d/2

*{AI05-0123-1}* For a derived type whose parent is an untagged record type, predefined equality is defined in terms of the primitive (possibly user-defined) equals operator of the parent type.

14.1/3

**Reason:** This prevents predefined equality from reemerging in generic units for untagged record types. For other uses the primitive equality is inherited and the inherited routine is primitive.

14.e/3

*{AI05-0123-1}* For a private type, if its full type is a record type, predefined equality is defined in terms of the primitive equals operator of the full type; otherwise, predefined equality for the private type is that of its full type.

15/3

For other composite types, the predefined equality operators [(and certain other predefined operations on composite types — see 4.5.1 and 4.6)] are defined in terms of the corresponding operation on *matching components*, defined as follows:

16

- For two composite objects or values of the same non-array type, matching components are those that correspond to the same `component_declaration` or `discriminant_specification`;
- For two one-dimensional arrays of the same type, matching components are those (if any) whose index values match in the following sense: the lower bounds of the index ranges are defined to match, and the successors of matching indices are defined to match;
- For two multidimensional arrays of the same type, matching components are those whose index values match in successive index positions.

17

18

19

The analogous definitions apply if the types of the two objects or values are convertible, rather than being the same.

20

**Discussion:** Ada 83 seems to omit this part of the definition, though it is used in array type conversions. See 4.6.

20.a

Given the above definition of matching components, the result of the predefined equals operator for composite types (other than for those composite types covered earlier) is defined as follows:

21

- If there are no components, the result is defined to be True;
- If there are unmatched components, the result is defined to be False;
- *{AI05-0123-1}* Otherwise, the result is defined in terms of the primitive equals operator for any matching components that are records, and the predefined equals for any other matching components.

22

23

24/3

**Reason:** *{AI05-0123-1}* This asymmetry between components with and without a record type is necessary to preserve most upward compatibility and corresponds with the corresponding situation with generics, where the predefined operations “reemerge” in a generic for non-record types, but do not for record types. Also, only tagged types support user-defined assignment (see 7.6), so only tagged types can fully handle levels of indirection in the implementation of the type. For untagged types, one reason for a user-defined equals operator might be to allow values with different bounds or discriminants to compare equal in certain cases. When such values are matching components, the bounds or discriminants will necessarily match anyway if the discriminants of the enclosing values match.

24.a/3

**Ramification:** Two null arrays of the same type are always equal; two null records of the same type are always equal.

24.b

*{AI05-0123-1}* Note that if a composite object has a component of a floating point type, and the floating point type has both a plus and minus zero, which are considered equal by the predefined equality, then a block compare cannot be used for the predefined composite equality. Of course, with user-defined equals operators for components that are records, a block compare breaks down anyway, so this is not the only special case that requires component-by-component comparisons. On a one's complement machine, a similar situation might occur for integer types, since one's complement machines typically have both a plus and minus (integer) zero.

24.c/3

- 24.d/2        **To be honest:** {AI95-00230-01} For a component with an anonymous access type, “predefined equality” is that defined for the *universal\_access* type (anonymous access types have no equality operators of their own).
- 24.e/3        {AI05-0123-1} For a component with a record type *T*, “the primitive equals operator” is the one with two parameters of *T* which returns Boolean. We’re not talking about some random other primitive function named “=”.
- 24.1/3        {AI05-0123-1} If the primitive equals operator for an untagged record type is abstract, then `Program_Error` is raised at the point of any (implicit) call to that abstract subprogram.
- 24.f/3        **Reason:** An explicit call to an abstract subprogram is illegal. This rule is needed in order to define the effect of an implicit call such as a call that is part of the predefined equality operation for an enclosing composite type that has a component of an untagged record type that has an abstract primitive equals operator. For tagged types, an abstract primitive equals operator is only allowed for an abstract type, and abstract types cannot be components, so this case does not occur.
- 24.2/1        {8652/0016} {AI95-00123-01} For any composite type, the order in which “=” is called for components is unspecified. Furthermore, if the result can be determined before calling “=” on some components, it is unspecified whether “=” is called on those components.
- 25        The predefined “/=” operator gives the complementary result to the predefined “=” operator.
- 25.a        **Ramification:** Furthermore, if the user defines an “=” operator that returns Boolean, then a “/=” operator is implicitly declared in terms of the user-defined “=” operator so as to give the complementary result. See 6.6.
- 26/3        {AI05-0264-1} For a discrete array type, the predefined ordering operators correspond to *lexicographic order* using the predefined order relation of the component type: A null array is lexicographically less than any array having at least one component. In the case of nonnull arrays, the left operand is lexicographically less than the right operand if the first component of the left operand is less than that of the right; otherwise, the left operand is lexicographically less than the right operand only if their first components are equal and the tail of the left operand is lexicographically less than that of the right (the *tail* consists of the remaining components beyond the first and can be null).
- 26.1/3        {AI05-0269-1} An *individual membership test* is the membership test of a single `membership_choice`.
- 27/3        {AI05-0158-1} For the evaluation of a membership test using `in` whose `membership_choice_list` has a single `membership_choice`, the `simple_expression` and the `membership_choice` are evaluated in an arbitrary order; the result is the result of the individual membership test for the `membership_choice`.
- 27.1/3        {AI05-0158-1} For the evaluation of a membership test using `in` whose `membership_choice_list` has more than one `membership_choice`, the `simple_expression` of the membership test is evaluated first and the result of the operation is equivalent to that of a sequence consisting of an individual membership test on each `membership_choice` combined with the short-circuit control form `or else`.
- 27.a.1/3        **Ramification:** {AI05-0158-1} This equivalence includes the evaluation of the `membership_choices`; evaluation stops as soon as an individual choice evaluates to True.
- 28/3        {AI05-0158-1} {AI05-0269-1} An individual membership test yields the result True if:
- 28.1/3        • {AI05-0158-1} {AI05-0264-1} The `membership_choice` is a `choice_expression`, and the `simple_expression` is equal to the value of the `membership_choice`. If the tested type is a record type or a limited type, the test uses the primitive equality for the type; otherwise, the test uses predefined equality.
- 28.2/3        • {AI05-0153-3} {AI05-0158-1} The `membership_choice` is a `range` and the value of the `simple_expression` belongs to the given range.
- 29/3        • {AI05-0153-3} {AI05-0158-1} The `membership_choice` is a `subtype_mark`, the tested type is scalar, the value of the `simple_expression` belongs to the range of the named subtype, and the predicate of the named subtype evaluates to True.
- 29.a/3        **Ramification:** {AI05-0153-3} The scalar membership test only does a range check and a predicate check. It does not perform any other check, such as whether a value falls in a “hole” of a “holey” enumeration type. The `Pos` attribute function can be used for that purpose.

- Even though `Standard.Float` is an unconstrained subtype, the test “`X in Float`” will still return `False` (presuming the evaluation of `X` does not raise `Constraint_Error`) when `X` is outside `Float'Range`. 29.b
- `{AI95-00231-01}` `{AI05-0153-3}` `{AI05-0158-1}` The `membership_choice` is a `subtype_mark`, the tested type is not scalar, the value of the `simple_expression` satisfies any constraints of the named subtype, the predicate of the named subtype evaluates to `True`, and: 30/3
    - `{AI95-00231-01}` if the type of the `simple_expression` is class-wide, the value has a tag that identifies a type covered by the tested type; 30.1/2
 

**Ramification:** Note that the tag is not checked if the `simple_expression` is of a specific type. 30.a
    - `{AI95-00231-01}` `{AI05-0149-1}` if the tested type is an access type and the named subtype excludes `null`, the value of the `simple_expression` is not `null`; 30.2/3
    - `{AI05-0149-1}` if the tested type is a general access-to-object type, the type of the `simple_expression` is convertible to the tested type and its accessibility level is no deeper than that of the tested type; further, if the designated type of the tested type is tagged and the `simple_expression` is nonnull, the tag of the object designated by the value of the `simple_expression` is covered by the designated type of the tested type. 30.3/3
- `{AI05-0264-1}` Otherwise, the test yields the result `False`. 31/3
- A membership test using **not in** gives the complementary result to the corresponding membership test using **in**. 32
- To be honest:** `{AI05-0158-1}` `X not in A | B | C` is intended to be exactly equivalent to `not (X in A | B | C)`, including the order of evaluation of the `simple_expression` and `membership_choices`. 32.a/3

#### *Implementation Requirements*

- `{8652/0016}` `{AI95-00123-01}` For all nonlimited types declared in language-defined packages, the “`=`” and “`/=`” operators of the type shall behave as if they were the predefined equality operators for the purposes of the equality of composite types and generic formal types. 32.1/1
- Ramification:** `{AI95-00123-01}` `{AI05-0123-1}` If any language-defined types are implemented with a user-defined “`=`” operator, then either the full type must be a record type, or the compiler must use “magic” to implement equality for this type. A normal user-defined “`=`” operator for a non-record type does *not* meet this requirement. 32.a.1/3

#### NOTES

*This paragraph was deleted.* `{AI95-00230-01}` 33/2

13 If a composite type has components that depend on discriminants, two values of this type have matching components if and only if their discriminants are equal. Two nonnull arrays have matching components if and only if the length of each dimension is the same for both. 34

#### *Examples*

- Examples of expressions involving relational operators and membership tests:* 35
- ```
X /= Y 36
" " < "A" and "A" < "Aa" -- True 37
"Aa" < "B" and "A" < "A " -- True

{AI05-0264-1} My_Car = null -- True if My_Car has been set to null (see 3.10.1) 38/3
My_Car = Your_Car -- True if we both share the same car
My_Car.all = Your_Car.all -- True if the two cars are identical

{AI05-0158-1} N not in 1 .. 10 -- range membership test 39/3
Today in Mon .. Fri -- range membership test
Today in Weekday -- subtype membership test (see 3.5.1)
Card in Clubs | Spades -- list membership test (see 3.5.1)
Archive in Disk_Unit -- subtype membership test (see 3.8.1)
Tree.all in Addition'Class -- class membership test (see 3.9.1)
```

Extensions to Ada 83

- Membership tests can be used to test the tag of a class-wide value. 39.a

- 39.b Predefined equality for a composite type is defined in terms of the primitive equals operator for tagged components or the parent part.

Wording Changes from Ada 83

- 39.c The term “membership test” refers to the relation "X in S" rather to simply the reserved word **in** or **not in**.
- 39.d We use the term “equality operator” to refer to both the = (equals) and /= (not equals) operators. Ada 83 referred to = as *the* equality operator, and /= as the inequality operator. The new wording is more consistent with the ISO 10646 name for "=" (equals sign) and provides a category similar to “ordering operator” to refer to both = and /=.
- 39.e We have changed the term “catenate” to “concatenate”.

Extensions to Ada 95

- 39.f/2 {AI95-00230-01} {AI95-00420-01} The *universal_access* equality operators are new. They provide equality operations (most importantly, testing against **null**) for anonymous access types.

Wording Changes from Ada 95

- 39.g/2 {8652/0016} {AI95-00123-01} **Corrigendum:** Wording was added to clarify that the order of calls (and whether the calls are made at all) on "=" for components is unspecified. Also clarified that "=" must compose properly for language-defined types.
- 39.h/2 {AI95-00251-01} Memberships were adjusted to allow interfaces which don't cover the tested type, in order to be consistent with type conversions.

Inconsistencies With Ada 2005

- 39.i/3 {AI05-0123-1} User-defined untagged record equality is now defined to compose and be used in generics. Any code which assumes that the predefined equality reemerges in generics and in predefined equals for composite types could fail. However, it is much more likely that this change will fix bugs, as the behavior that would be expected (the user-defined "=" is used) will be true in more cases.
- 39.j/3 {AI05-0123-1} If a composite type contains a component of an untagged record type with an abstract equality operation, calling "=" on the composite type will raise `Program_Error`, while in the past a result will be returned using the predefined equality. This is quite possible in ASIS programs; it will detect a bug in such programs but of course the programs will need to be fixed before they will work.

Incompatibilities With Ada 2005

- 39.k/3 {AI05-0123-1} Late and hidden overriding of equality for untagged record types is now prohibited. This is necessary to make composition of equality predictable. It should always be possible to move the overriding to an earlier spot where it will be legal.

Extensions to Ada 2005

- 39.l/3 {AI05-0149-1} Membership tests for valid accessibility levels and tag coverage by the designated type for general access types are new.
- 39.m/3 {AI05-0153-3} Membership tests now include a predicate check.
- 39.n/3 {AI05-0158-1} Membership tests now allow multiple choices.

Wording Changes from Ada 2005

- 39.o/3 {AI05-0020-1} **Correction:** Wording was added to clarify that *universal_access* "=" does not apply if an appropriate operator is declared for a partial or incomplete view of the designated type. Otherwise, adding a partial or incomplete view could make some "=" operators ambiguous.

4.5.3 Binary Adding Operators

Static Semantics

- 1 The binary adding operators + (addition) and – (subtraction) are predefined for every specific numeric type *T* with their conventional meaning. They have the following specifications:

- 2 `function "+" (Left, Right : T) return T`
`function "-" (Left, Right : T) return T`

The concatenation operators & are predefined for every nonlimited, one-dimensional array type T with component type C . They have the following specifications: 3

```
function "&" (Left : T; Right : T) return T
function "&" (Left : T; Right : C) return T
function "&" (Left : C; Right : T) return T
function "&" (Left : C; Right : C) return T
```

4

Dynamic Semantics

For the evaluation of a concatenation with result type T , if both operands are of type T , the result of the concatenation is a one-dimensional array whose length is the sum of the lengths of its operands, and whose components comprise the components of the left operand followed by the components of the right operand. If the left operand is a null array, the result of the concatenation is the right operand. Otherwise, the lower bound of the result is determined as follows: 5

- If the ultimate ancestor of the array type was defined by a `constrained_array_definition`, then the lower bound of the result is that of the index subtype; 6
 - Reason:** This rule avoids `Constraint_Error` when using concatenation on an array type whose first subtype is constrained. 6.a
- If the ultimate ancestor of the array type was defined by an `unconstrained_array_definition`, then the lower bound of the result is that of the left operand. 7

[The upper bound is determined by the lower bound and the length.] A check is made that the upper bound of the result of the concatenation belongs to the range of the index subtype, unless the result is a null array. `Constraint_Error` is raised if this check fails. 8

If either operand is of the component type C , the result of the concatenation is given by the above rules, using in place of such an operand an array having this operand as its only component (converted to the component subtype) and having the lower bound of the index subtype of the array type as its lower bound. 9

Ramification: The conversion might raise `Constraint_Error`. The conversion provides “sliding” for the component in the case of an array-of-arrays, consistent with the normal Ada 95 rules that allow sliding during parameter passing. 9.a

The result of a concatenation is defined in terms of an assignment to an anonymous object, as for any function call (see 6.5). 10

Ramification: This implies that value adjustment is performed as appropriate — see 7.6. We don't bother saying this for other predefined operators, even though they are all function calls, because this is the only one where it matters. It is the only one that can return a value having controlled parts. 10.a

NOTES

14 As for all predefined operators on modular types, the binary adding operators + and – on modular types include a final reduction modulo the modulus if the result is outside the base range of the type. 11

Implementation Note: A full “modulus” operation need not be performed after addition or subtraction of modular types. For binary moduli, a simple mask is sufficient. For nonbinary moduli, a check after addition to see if the value is greater than the high bound of the base range can be followed by a conditional subtraction of the modulus. Conversely, a check after subtraction to see if a “borrow” was performed can be followed by a conditional addition of the modulus. 11.a

Examples

Examples of expressions involving binary adding operators: 12

```
Z + 0.1      -- Z has to be of a real type
"A" & "BCD"  -- concatenation of two string literals
'A' & "BCD"  -- concatenation of a character literal and a string literal
'A' & 'A'    -- concatenation of two character literals
```

13
14

Inconsistencies With Ada 83

- 14.a The lower bound of the result of concatenation, for a type whose first subtype is constrained, is now that of the index subtype. This is inconsistent with Ada 83, but generally only for Ada 83 programs that raise `Constraint_Error`. For example, the concatenation operator in
- 14.b

```
X : array(1..10) of Integer;
begin
X := X(6..10) & X(1..5);
```
- 14.c would raise `Constraint_Error` in Ada 83 (because the bounds of the result of the concatenation would be 6..15, which is outside of 1..10), but would succeed and swap the halves of X (as expected) in Ada 95.

Extensions to Ada 83

- 14.d Concatenation is now useful for array types whose first subtype is constrained. When the result type of a concatenation is such an array type, `Constraint_Error` is avoided by effectively first sliding the left operand (if nonnull) so that its lower bound is that of the index subtype.

4.5.4 Unary Adding Operators

Static Semantics

- 1 The unary adding operators `+` (identity) and `-` (negation) are predefined for every specific numeric type *T* with their conventional meaning. They have the following specifications:
- 2

```
function "+" (Right : T) return T
function "-" (Right : T) return T
```
- NOTES
- 3 15 For modular integer types, the unary adding operator `-`, when given a nonzero operand, returns the result of subtracting the value of the operand from the modulus; for a zero operand, the result is zero.

4.5.5 Multiplying Operators

Static Semantics

- 1 The multiplying operators `*` (multiplication), `/` (division), `mod` (modulus), and `rem` (remainder) are predefined for every specific integer type *T*:
- 2

```
function "*" (Left, Right : T) return T
function "/" (Left, Right : T) return T
function "mod" (Left, Right : T) return T
function "rem" (Left, Right : T) return T
```
- 3 Signed integer multiplication has its conventional meaning.
- 4 Signed integer division and remainder are defined by the relation:
- 5
$$A = (A/B) * B + (A \text{ rem } B)$$
- 6 where $(A \text{ rem } B)$ has the sign of *A* and an absolute value less than the absolute value of *B*. Signed integer division satisfies the identity:
- 7
$$(-A) / B = -(A / B) = A / (-B)$$
- 8/3 *{AI05-0260-1}* The signed integer modulus operator is defined such that the result of **A mod B** is either zero, or has the sign of *B* and an absolute value less than the absolute value of *B*; in addition, for some signed integer value *N*, this result satisfies the relation:
- 9
$$A = B * N + (A \text{ mod } B)$$
- 10 The multiplying operators on modular types are defined in terms of the corresponding signed integer operators[, followed by a reduction modulo the modulus if the result is outside the base range of the type] [(which is only possible for the "*" operator)].

- Ramification:** The above identity satisfied by signed integer division is not satisfied by modular division because of the difference in effect of negation. 10.a
- Multiplication and division operators are predefined for every specific floating point type *T*: 11
- ```
function "*" (Left, Right : T) return T 12
function "/" (Left, Right : T) return T
```
- The following multiplication and division operators, with an operand of the predefined type Integer, are predefined for every specific fixed point type *T*: 13
- ```
function "*" (Left : T; Right : Integer) return T 14
function "*" (Left : Integer; Right : T) return T
function "/" (Left : T; Right : Integer) return T
```
- [All of the above multiplying operators are usable with an operand of an appropriate universal numeric type.] The following additional multiplying operators for *root_real* are predefined[, and are usable when both operands are of an appropriate universal or root numeric type, and the result is allowed to be of type *root_real*, as in a *number_declaration*]: 15
- Ramification:** These operators are analogous to the multiplying operators involving fixed or floating point types where *root_real* substitutes for the fixed or floating point type, and *root_integer* substitutes for Integer. Only values of the corresponding universal numeric types are implicitly convertible to these root numeric types, so these operators are really restricted to use with operands of a universal type, or the specified root numeric types. 15.a
- ```
function "*" (Left, Right : root_real) return root_real 16
function "/" (Left, Right : root_real) return root_real
function "*" (Left : root_real; Right : root_integer) return root_real 17
function "*" (Left : root_integer; Right : root_real) return root_real
function "/" (Left : root_real; Right : root_integer) return root_real
```
- Multiplication and division between any two fixed point types are provided by the following two predefined operators: 18
- Ramification:** *Universal\_fixed* is the universal type for the class of fixed point types, meaning that these operators take operands of any fixed point types (not necessarily the same) and return a result that is implicitly (or explicitly) convertible to any fixed point type. 18.a
- ```
function "*" (Left, Right : universal_fixed) return universal_fixed 19
function "/" (Left, Right : universal_fixed) return universal_fixed
```
- Name Resolution Rules*
- {AI95-00364-01} {AI95-00420-01} The above two fixed-fixed multiplying operators shall not be used in a context where the expected type for the result is itself *universal_fixed* [— the context has to identify some other numeric type to which the result is to be converted, either explicitly or implicitly]. Unless the predefined universal operator is identified using an expanded name with prefix denoting the package Standard, an explicit conversion is required on the result when using the above fixed-fixed multiplication operator if either operand is of a type having a user-defined primitive multiplication operator such that: 19.1/2
- {AI05-0020-1} {AI05-0209-1} it is declared immediately within the same declaration list as the type or any partial or incomplete view thereof; and 19.2/3
 - both of its formal parameters are of a fixed-point type. 19.3/2
- {AI95-00364-01} {AI95-00420-01} A corresponding requirement applies to the universal fixed-fixed division operator. 19.4/2
- Discussion:** The *small* of *universal_fixed* is infinitesimal; no loss of precision is permitted. However, fixed-fixed division is impractical to implement when an exact result is required, and multiplication will sometimes result in unanticipated overflows in such circumstances, so we require an explicit conversion to be inserted in expressions like *A * B * C* if *A*, *B*, and *C* are each of some fixed point type. 19.a/2
- On the other hand, *X := A * B*; is permitted by this rule, even if *X*, *A*, and *B* are all of different fixed point types, since the expected type for the result of the multiplication is the type of *X*, which is necessarily not *universal_fixed*. 19.b/2

19.c/2 {AI95-00364-01} {AI95-00420-01} We have made these into Name Resolution rules to ensure that user-defined primitive fixed-fixed operators are not made unusable due to the presence of these universal fixed-fixed operators. But we do allow these operators to be used if prefixed by package Standard, so that they can be used in the definitions of user-defined operators.

Paragraph 20 was deleted.

Dynamic Semantics

21 The multiplication and division operators for real types have their conventional meaning. [For floating point types, the accuracy of the result is determined by the precision of the result type. For decimal fixed point types, the result is truncated toward zero if the mathematical result is between two multiples of the *small* of the specific result type (possibly determined by context); for ordinary fixed point types, if the mathematical result is between two multiples of the *small*, it is unspecified which of the two is the result.]

22 The exception Constraint_Error is raised by integer division, **rem**, and **mod** if the right operand is zero. [Similarly, for a real type *T* with *T*Machine_Overflows True, division by zero raises Constraint_Error.]

NOTES

23 16 For positive A and B, A/B is the quotient and A **rem** B is the remainder when A is divided by B. The following relations are satisfied by the rem operator:

24
$$\begin{aligned} A \text{ rem } (-B) &= A \text{ rem } B \\ (-A) \text{ rem } B &= -(A \text{ rem } B) \end{aligned}$$

25 17 For any signed integer K, the following identity holds:

26
$$A \text{ mod } B = (A + K*B) \text{ mod } B$$

27 The relations between signed integer division, remainder, and modulus are illustrated by the following table:

	A	B	A/B	A rem B	A mod B	A	B	A/B	A rem B	A mod B
28	10	5	2	0	0	-10	5	-2	0	0
29	11	5	2	1	1	-11	5	-2	-1	4
	12	5	2	2	2	-12	5	-2	-2	3
	13	5	2	3	3	-13	5	-2	-3	2
	14	5	2	4	4	-14	5	-2	-4	1
30	A	B	A/B	A rem B	A mod B	A	B	A/B	A rem B	A mod B
	10	-5	-2	0	0	-10	-5	2	0	0
	11	-5	-2	1	-4	-11	-5	2	-1	-1
	12	-5	-2	2	-3	-12	-5	2	-2	-2
	13	-5	-2	3	-2	-13	-5	2	-3	-3
	14	-5	-2	4	-1	-14	-5	2	-4	-4

Examples

31 *Examples of expressions involving multiplying operators:*

```

32 I : Integer := 1;
   J : Integer := 2;
   K : Integer := 3;

33 X : Real := 1.0;           -- see 3.5.7
   Y : Real := 2.0;

34 F : Fraction := 0.25;     -- see 3.5.9
   G : Fraction := 0.5;
    
```

<i>Expression</i>	<i>Value</i>	<i>Result Type</i>	
$I * J$	2	same as I and J , that is, Integer	
K / J	1	same as K and J , that is, Integer	
$K \bmod J$	1	same as K and J , that is, Integer	
X / Y	0.5	same as X and Y , that is, Real	
$F / 2$	0.125	same as F , that is, Fraction	
$3 * F$	0.75	same as F , that is, Fraction	
$0.75 * G$	0.375	universal_fixed, implicitly convertible to any fixed point type	
Fraction($F * G$)	0.125	Fraction, as stated by the conversion	
Real($J * Y$)	4.0	Real, the type of both operands after conversion of J	

Incompatibilities With Ada 83

{AI95-00364-01} {AI95-00420-01} The universal fixed-fixed multiplying operators are now directly available (see below). Any attempt to use user-defined fixed-fixed multiplying operators will be ambiguous with the universal ones. The only way to use the user-defined operators is to fully qualify them in a prefix call. This problem was not documented during the design of Ada 95, and has been mitigated by Ada 2005. 35.a.1/2

Extensions to Ada 83

Explicit conversion of the result of multiplying or dividing two fixed point numbers is no longer required, provided the context uniquely determines some specific fixed point result type. This is to improve support for decimal fixed point, where requiring explicit conversion on every fixed-fixed multiply or divide was felt to be inappropriate. 35.a

The type *universal_fixed* is covered by *universal_real*, so real literals and fixed point operands may be multiplied or divided directly, without any explicit conversions required. 35.b

Wording Changes from Ada 83

We have used the normal syntax for function definition rather than a tabular format. 35.c

Incompatibilities With Ada 95

{AI95-00364-01} We have changed the resolution rules for the universal fixed-fixed multiplying operators to remove the incompatibility with Ada 83 discussed above. The solution is to hide the universal operators in some circumstances. As a result, some legal Ada 95 programs will require the insertion of an explicit conversion around a fixed-fixed multiply operator. This change is likely to catch as many bugs as it causes, since it is unlikely that the user wanted to use predefined operators when they had defined user-defined versions. 35.d/2

Wording Changes from Ada 2005

{AI05-0020-1} {AI05-0209-1} **Correction:** Wording was added to clarify that *universal_fixed* "*" and "/" does not apply if an appropriate operator is declared for a partial (or incomplete) view of the designated type. Otherwise, adding a partial (or incomplete) view could make some "*" and "/" operators ambiguous. 35.e/3

{AI05-0260-1} **Correction:** The wording for the **mod** operator was corrected so that a result of 0 does not have to have "the sign of B" (which is impossible if B is negative). 35.f/3

4.5.6 Highest Precedence Operators

Static Semantics

The highest precedence unary operator **abs** (absolute value) is predefined for every specific numeric type T , with the following specification: 1

```
function "abs" (Right : T) return T 2
```

The highest precedence unary operator **not** (logical negation) is predefined for every boolean type T , every modular type T , and for every one-dimensional array type T whose components are of a boolean type, with the following specification: 3

```
function "not" (Right : T) return T 4
```

5 The result of the operator **not** for a modular type is defined as the difference between the high bound of the base range of the type and the value of the operand. [For a binary modulus, this corresponds to a bit-wise complement of the binary representation of the value of the operand.]

6 The operator **not** that applies to a one-dimensional array of boolean components yields a one-dimensional boolean array with the same bounds; each component of the result is obtained by logical negation of the corresponding component of the operand (that is, the component that has the same index value). A check is made that each component of the result belongs to the component subtype; the exception `Constraint_Error` is raised if this check fails.

6.a **Discussion:** The check against the component subtype is per AI83-00535.

7 The highest precedence *exponentiation* operator ****** is predefined for every specific integer type *T* with the following specification:

8 `function "**" (Left : T; Right : Natural) return T`

9 Exponentiation is also predefined for every specific floating point type as well as *root_real*, with the following specification (where *T* is *root_real* or the floating point type):

10 `function "**" (Left : T; Right : Integer'Base) return T`

11/3 {AI05-0088-1} The right operand of an exponentiation is the *exponent*. The value of X^{**N} with the value of the exponent *N* positive is the same as the value of $X * X * \dots * X$ (with *N*-1 multiplications) except that the multiplications are associated in an arbitrary order. With *N* equal to zero, the result is one. With the value of *N* negative [(only defined for a floating point operand)], the result is the reciprocal of the result using the absolute value of *N* as the exponent.

11.a **Ramification:** The language does not specify the order of association of the multiplications inherent in an exponentiation. For a floating point type, the accuracy of the result might depend on the particular association order chosen.

Implementation Permissions

12 The implementation of exponentiation for the case of a negative exponent is allowed to raise `Constraint_Error` if the intermediate result of the repeated multiplications is outside the safe range of the type, even though the final result (after taking the reciprocal) would not be. (The best machine approximation to the final result in this case would generally be 0.0.)

NOTES

13 18 As implied by the specification given above for exponentiation of an integer type, a check is made that the exponent is not negative. `Constraint_Error` is raised if this check fails.

Inconsistencies With Ada 83

13.a.1/1 {8652/0100} {AI95-00018-01} The definition of ****** allows arbitrary association of the multiplications which make up the result. Ada 83 required left-to-right associations (confirmed by AI83-00137). Thus it is possible that ****** would provide a slightly different (and more potentially accurate) answer in Ada 95 than in the same Ada 83 program.

Wording Changes from Ada 83

13.a We now show the specification for ****** for integer types with a parameter subtype of `Natural` rather than `Integer` for the exponent. This reflects the fact that `Constraint_Error` is raised if a negative value is provided for the exponent.

Wording Changes from Ada 2005

13.b/3 {AI05-0088-1} **Correction:** The equivalence definition for ****** was corrected so that it does not imply that the operands are evaluated multiple times.

4.5.7 Conditional Expressions

1/3 {AI05-0147-1} {AI05-0188-1} {AI05-0262-1} A `conditional_expression` selects for evaluation at most one of the enclosed *dependent_expressions*, depending on a decision among the alternatives. One kind of

`conditional_expression` is the `if_expression`, which selects for evaluation a *dependent_expression* depending on the value of one or more corresponding conditions. The other kind of `conditional_expression` is the `case_expression`, which selects for evaluation one of a number of alternative *dependent_expressions*; the chosen alternative is determined by the value of a *selecting_expression*.

Language Design Principles

{AI05-0188-1} As previously noted, there are two kinds of `conditional_expression`, `if_expressions` and `case_expressions`. Whenever possible, we have written the rules in terms of `conditional_expressions` to avoid duplication. 1.a/3

{AI05-0147-1} The rules for `conditional_expressions` have been designed as much as possible to work similarly to a parenthesized expression. The intent is that as much as possible, wherever a parenthesized expression would be allowed, a `conditional_expression` would be allowed, and it should work the same way. 1.b/3

Syntax

{AI05-0188-1} `conditional_expression ::= if_expression | case_expression` 2/3

{AI05-0147-1} {AI05-0188-1} `if_expression ::=`
if `condition` **then** *dependent_expression*
 {**elsif** `condition` **then** *dependent_expression*}
 [**else** *dependent_expression*]

{AI05-0147-1} `condition ::= boolean_expression` 4/3

{AI05-0188-1} `case_expression ::=`
case *selecting_expression* **is**
`case_expression_alternative` {,
`case_expression_alternative`}

{AI05-0188-1} `case_expression_alternative ::=`
when `discrete_choice_list =>`
dependent_expression 6/3

{AI05-0147-1} Wherever the Syntax Rules allow an expression, a `conditional_expression` may be used in place of the expression, so long as it is immediately surrounded by parentheses. 7/3

Discussion: {AI05-0147-1} The syntactic category `conditional_expression` appears only as a primary that is parenthesized. The above rule allows it to additionally be used in other contexts where it would be directly surrounded by parentheses. 7.a/3

The grammar makes the following directly legal: 7.b/3

A := (if X then Y else Z); -- parentheses required 7.c/3
 A := B + (if X then Y else Z) + C; -- parentheses required

The following procedure calls are syntactically legal; the first uses the above rule to eliminate the redundant parentheses found in the second: 7.d/3

P(if X then Y else Z); 7.e/3
 P((if X then Y else Z)); -- redundant parentheses
 P((if X then Y else Z), Some_Other_Param); 7.f/3
 P(Some_Other_Param, (if X then Y else Z));
 P(Formal => (if X then Y else Z));

whereas the following are illegal: 7.g/3

P(if X then Y else Z, Some_Other_Param); 7.h/3
 P(Some_Other_Param, if X then Y else Z);
 P(Formal => if X then Y else Z);

because in these latter cases, the `conditional_expression` is not immediately surrounded by parentheses (which means on both sides!). 7.i/3

The English-language rule applies in all places that could surround an expression with parentheses, including pragma arguments, type conversion and qualified expression operands, and array index expressions. 7.j/3

This English-language rule could have been implemented instead by adding a nonterminal `expression_within_parentheses`, which would consist of expressions and `conditional_expressions`. Then, that could 7.k/3

be used in all of the syntax which could consist of parens directly around an expression. We did not do that because of the large amount of change required. A complete grammar is given in AI05-0147-1.

7.1/3 **Implementation Note:** {AI05-0147-1} Implementers are cautioned to consider error detection when implementing the syntax for conditional_expressions. An if_expression and an if_statement are very similar syntactically, (as are a case_expression and a case_statement) and simple mistakes can appear to change one into the other, potentially causing errors to be moved far away from their actual location. The absence of **end if** to terminate an if_expression (and **end case** for a case_expression) also may make error handling harder.

Name Resolution Rules

8/3 {AI05-0147-1} If a conditional_expression is expected to be of a type T , then each dependent_expression of the conditional_expression is expected to be of type T . Similarly, if a conditional_expression is expected to be of some class of types, then each dependent_expression of the conditional_expression is subject to the same expectation. If a conditional_expression shall resolve to be of a type T , then each dependent_expression shall resolve to be of type T .

9/3 {AI05-0147-1} The possible types of a conditional_expression are further determined as follows:

10/3 • If the conditional_expression is the operand of a type conversion, the type of the conditional_expression is the target type of the conversion; otherwise,

10.a/3 **Reason:** This rule distributes an enclosing type conversion to the dependent_expressions. This means that

10.b/3 $T(\text{if } C \text{ then } A \text{ else } B)$

10.c/3 has the same semantics as

10.d/3 $(\text{if } C \text{ then } T(A) \text{ else } T(B))$

11/3 • If all of the dependent_expressions are of the same type, the type of the conditional_expression is that type; otherwise,

12/3 • If a dependent_expression is of an elementary type, the type of the conditional_expression shall be covered by that type; otherwise,

12.a/3 **Reason:** This rule supports the use of numeric literals and universal expressions within a conditional_expression.

13/3 • If the conditional_expression is expected to be of type T or shall resolve to type T , then the conditional_expression is of type T .

13.a/3 **Ramification:** If the type of the conditional_expression cannot be determined by one of these rules, then Name Resolution has failed for that expression, even if the dependent_expressions would resolve individually.

14/3 {AI05-0147-1} A condition is expected to be of any boolean type.

15/3 {AI05-0188-1} The expected type for the selecting_expression and the discrete_choices are as for case statements (see 5.4).

Legality Rules

16/3 {AI05-0147-1} {AI05-0188-1} All of the dependent_expressions shall be convertible (see 4.6) to the type of the conditional_expression.

17/3 {AI05-0147-1} {AI05-0188-1} {AI05-0269-1} If the expected type of a conditional_expression is a specific tagged type, all of the dependent_expressions of the conditional_expression shall be dynamically tagged, or none shall be dynamically tagged. In this case, the conditional_expression is dynamically tagged if all of the dependent_expressions are dynamically tagged, is tag-indeterminate if all of the dependent_expressions are tag-indeterminate, and is statically tagged otherwise.

18/3 {AI05-0147-1} {AI05-0262-1} If there is no else_dependent_expression, the if_expression shall be of a boolean type.

19/3 {AI05-0188-1} {AI05-0269-1} All Legality Rules that apply to the discrete_choices of a case_statement (see 5.4) also apply to the discrete_choices of a case_expression except within an instance of a generic unit.

Reason: The exemption for a case expression that occurs in an instance allows the following example: 19.a/3

```

generic
  with function Int_Func return Integer;
package G is
  X : Float := (case Int_Func is
                when Integer'First .. -1 => -1.0,
                when 0 => 0.0,
                when Positive => 1.0);
end G;
function Nat_Func return Natural is (123);
package I is new G (Int_Func => Nat_Func); -- Legal

```

19.b/3

19.c/3

19.d/3

Note that the Legality Rules still apply in the generic unit itself; they are just not enforced in an instance of the unit. 19.e/3

Dynamic Semantics

{AI05-0147-1} {AI05-0188-1} For the evaluation of an `if_expression`, the condition specified after `if`, and any conditions specified after `elsif`, are evaluated in succession (treating a final `else` as `elsif True then`), until one evaluates to True or all conditions are evaluated and yield False. If a condition evaluates to True, the associated *dependent* expression is evaluated, converted to the type of the `if_expression`, and the resulting value is the value of the `if_expression`. Otherwise (when there is no `else` clause), the value of the `if_expression` is True. 20/3

Ramification: `Else` is required unless the `if_expression` has a boolean type, so the last sentence can only apply to `if_expressions` with a boolean type. 20.a/3

{AI05-0188-1} For the evaluation of a `case_expression`, the *selecting_expression* is first evaluated. If the value of the *selecting_expression* is covered by the `discrete_choice_list` of some `case_expression_alternative`, then the *dependent_expression* of the `case_expression_alternative` is evaluated, converted to the type of the `case_expression`, and the resulting value is the value of the `case_expression`. Otherwise (the value is not covered by any `discrete_choice_list`, perhaps due to being outside the base range), `Constraint_Error` is raised. 21/3

Extensions to Ada 2005

{AI05-0147-1} If expressions and case expressions are new. 21.a/3

4.5.8 Quantified Expressions

Syntax

```

{AI05-0176-1} quantified_expression ::=
for quantifier loop_parameter_specification => predicate
| for quantifier iterator_specification => predicate
quantifier ::= all | some
predicate ::= boolean_expression

```

1/3

2/3

3/3

{AI05-0176-1} Wherever the Syntax Rules allow an `expression`, a `quantified_expression` may be used in place of the `expression`, so long as it is immediately surrounded by parentheses. 4/3

Discussion: The syntactic category `quantified_expression` appears only as a primary that is parenthesized. The above rule allows it to additionally be used in other contexts where it would be directly surrounded by parentheses. This is the same rule that is used for `conditional_expressions`; see 4.5.7 for a detailed discussion of the meaning and effects of this rule. 4.a/3

Name Resolution Rules

{AI05-0176-1} The expected type of a `quantified_expression` is any Boolean type. The predicate in a `quantified_expression` is expected to be of the same type. 5/3

Dynamic Semantics

6/3 {AI05-0176-1} For the evaluation of a `quantified_expression`, the `loop_parameter_specification` or `iterator_specification` is first elaborated. The evaluation of a `quantified_expression` then evaluates the `predicate` for each value of the loop parameter. These values are examined in the order specified by the `loop_parameter_specification` (see 5.5) or `iterator_specification` (see 5.5.2).

7/3 {AI05-0176-1} The value of the `quantified_expression` is determined as follows:

8/3 • If the **quantifier** is **all**, the expression is True if the evaluation of the `predicate` yields True for each value of the loop parameter. It is False otherwise. Evaluation of the `quantified_expression` stops when all values of the domain have been examined, or when the `predicate` yields False for a given value. Any exception raised by evaluation of the `predicate` is propagated.

8.a/3 **Ramification:** The expression is True if the domain contains no values.

9/3 • If the **quantifier** is **some**, the expression is True if the evaluation of the `predicate` yields True for some value of the loop parameter. It is False otherwise. Evaluation of the `quantified_expression` stops when all values of the domain have been examined, or when the `predicate` yields True for a given value. Any exception raised by evaluation of the `predicate` is propagated.

9.a/3 **Ramification:** The expression is False if the domain contains no values.

Examples

10/3 {AI05-0176-1} The postcondition for a sorting routine on an array `A` with an index subtype `T` can be written:

```
11/3 Post => (A'Length < 2 or else
           (for all I in A'First .. T'Pred(A'Last) => A (I) <= A (T'Succ (I))))
```

12/3 {AI05-0176-1} The assertion that a positive number is composite (as opposed to prime) can be written:

```
13/3 pragma Assert (for some X in 2 .. N / 2 => N mod X = 0);
```

Extensions to Ada 2005

13.a/3 {AI05-0176-1} Quantified expressions are new.

4.6 Type Conversions

1/3 {AI05-0299-1} [Explicit type conversions, both value conversions and view conversions, are allowed between closely related types as defined below. This subclause also defines rules for value and view conversions to a particular subtype of a type, both explicit ones and those implicit in other constructs.]

Syntax

```
2 type_conversion ::=
  subtype_mark(expression)
  | subtype_mark(name)
```

3 The *target subtype* of a `type_conversion` is the subtype denoted by the `subtype_mark`. The *operand* of a `type_conversion` is the `expression` or `name` within the parentheses; its type is the *operand type*.

4/3 {AI05-0299-1} One type is *convertible* to a second type if a `type_conversion` with the first type as operand type and the second type as target type is legal according to the rules of this subclause. Two types are convertible if each is convertible to the other.

4.a **Ramification:** Note that “convertible” is defined in terms of legality of the conversion. Whether the conversion would raise an exception at run time is irrelevant to this definition.

{8652/0017} {AI95-00184-01} {AI95-00330-01} A `type_conversion` whose operand is the name of an object is called a *view conversion* if both its target type and operand type are tagged, or if it appears in a call as an actual parameter of mode **out** or **in out**; other `type_conversions` are called *value conversions*. 5/2

Ramification: A view conversion to a tagged type can appear in any context that requires an object name, including in an object renaming, the prefix of a `selected_component`, and if the operand is a variable, on the left side of an `assignment_statement`. View conversions to other types only occur as actual parameters. Allowing view conversions of untagged types in all contexts seemed to incur an undue implementation burden. 5.a

{AI95-00330-01} A type conversion appearing as an **in out** parameter in a generic instantiation is not a view conversion; the second part of the rule only applies to subprogram calls, not instantiations. 5.b/2

Name Resolution Rules

The operand of a `type_conversion` is expected to be of any type. 6

Discussion: This replaces the "must be determinable" wording of Ada 83. This is equivalent to (but hopefully more intuitive than) saying that the operand of a `type_conversion` is a "complete context." 6.a

The operand of a view conversion is interpreted only as a **name**; the operand of a value conversion is interpreted as an **expression**. 7

Reason: This formally resolves the syntactic ambiguity between the two forms of `type_conversion`, not that it really matters. 7.a

Legality Rules

{AI95-00251-01} In a view conversion for an untagged type, the target type shall be convertible (back) to the operand type. 8/2

Reason: Untagged view conversions appear only as [**in**] **out** parameters. Hence, the reverse conversion must be legal as well. The forward conversion must be legal even for an **out** parameter, because (for example) actual parameters of an access type are always copied in anyway. 8.a/2

Paragraphs 9 through 20 were reorganized and moved below.

Discussion: {AI95-00251-01} The entire Legality Rules section has been reorganized to eliminate an unintentional incompatibility with Ada 83. In rare cases, a type conversion between two types related by derivation is not allowed by Ada 95, while it is allowed in Ada 83. The reorganization fixes this. Much of the wording of the legality section is unchanged, but it is reordered and reformatted. Because of the limitations of our tools, we had to delete and replace nearly the entire section. The text of Ada 95 paragraphs 8 through 12, 14, 15, 17, 19, 20, and 24 are unchanged (just moved); these are now 24.1 through 24.5, 24.12, 24.13, 24.17, 24.19, 24.20, and 8. 8.b/2

{AI95-00251-01} {AI05-0115-1} If there is a type (other than a root numeric type) that is an ancestor of both the target type and the operand type, or both types are class-wide types, then at least one of the following rules shall apply: 21/3

- {AI95-00251-01} The target type shall be untagged; or 21.1/2

- The operand type shall be covered by or descended from the target type; or 22

Ramification: This is a conversion toward the root, which is always safe. 22.a

- {AI95-00251-01} The operand type shall be a class-wide type that covers the target type; or 23/2

Ramification: This is a conversion of a class-wide type toward the leaves, which requires a tag check. See Dynamic Semantics. 23.a

{AI95-00251-01} These two rules imply that a conversion from an ancestor type to a type extension is not permitted, as this would require specifying the values for additional components, in general, and changing the tag. An `extension_aggregate` has to be used instead, constructing a new value, rather than converting an existing value. However, a conversion from the class-wide type rooted at an ancestor type is permitted; such a conversion just verifies that the operand's tag is a descendant of the target. 23.b/2

- {AI95-00251-01} The operand and target types shall both be class-wide types and the specific type associated with at least one of them shall be an interface type. 23.1/2

Ramification: We allow converting any class-wide type T'Class to or from a class-wide interface type even if the specific type T does not have an appropriate interface ancestor, because some extension of T might have the needed 23.c/2

ancestor. This is similar to a conversion of a class-wide type toward the leaves of the tree, and we need to be consistent. Of course, there is a run-time check that the actual object has the needed interface.

- 24./3 {AI95-00251-01} {AI05-0115-1} If there is no type (other than a root numeric type) that is the ancestor of both the target type and the operand type, and they are not both class-wide types, one of the following rules shall apply:
- 24.1/2 • {AI95-00251-01} If the target type is a numeric type, then the operand type shall be a numeric type.
 - 24.2/2 • {AI95-00251-01} If the target type is an array type, then the operand type shall be an array type. Further:
 - 24.3/2 • {AI95-00251-01} The types shall have the same dimensionality;
 - 24.4/2 • {AI95-00251-01} Corresponding index types shall be convertible;
 - 24.5/2 • {AI95-00251-01} The component subtypes shall statically match;
 - 24.6/2 • {AI95-00392-01} If the component types are anonymous access types, then the accessibility level of the operand type shall not be statically deeper than that of the target type;
 - 24.b/2 **Reason:** For unrelated array types, the component types could have different accessibility, and we had better not allow a conversion of a local type into a global type, in case the local type points at local objects. We don't need a check for other types of components; such components necessarily are for related types, and either have the same accessibility or (for access discriminants) cannot be changed so the discriminant check will prevent problems.
 - 24.7/2 • {AI95-00246-01} Neither the target type nor the operand type shall be limited;
 - 24.c/2 **Reason:** We cannot allow conversions between unrelated limited types, as they may have different representations, and (since the types are limited), a copy cannot be made to reconcile the representations.
 - 24.8/2 • {AI95-00251-01} {AI95-00363-01} If the target type of a view conversion has aliased components, then so shall the operand type; and
 - 24.d/2 **Reason:** {AI95-00363-01} We cannot allow a view conversion from an object with unaliased components to an object with aliased components, because that would effectively allow pointers to unaliased components. This rule was missing from Ada 95.
 - 24.9/2 • {AI95-00246-01} {AI95-00251-01} The operand type of a view conversion shall not have a tagged, private, or volatile subcomponent.
 - 24.e/2 **Reason:** {AI95-00246-01} We cannot allow view conversions between unrelated might-be-by-reference types, as they may have different representations, and a copy cannot be made to reconcile the representations.
 - 24.f/2 **Ramification:** These rules only apply to unrelated array conversions; different (weaker) rules apply to conversions between related types.
 - 24.10/2 • {AI95-00230-01} If the target type is *universal_access*, then the operand type shall be an access type.
 - 24.g/2 **Discussion:** Such a conversion cannot be written explicitly, of course, but it can be implicit (see below).
 - 24.11/2 • {AI95-00230-01} {AI95-00251-01} If the target type is a general access-to-object type, then the operand type shall be *universal_access* or an access-to-object type. Further, if the operand type is not *universal_access*:
 - 24.h/2 **Discussion:** The Legality Rules and Dynamic Semantics are worded so that a *type_conversion* T(X) (where T is an access type) is (almost) equivalent to the *attribute_reference* X.all'Access, where the result is of type T. The only difference is that the *type_conversion* accepts a null value, whereas the *attribute_reference* would raise *Constraint_Error*.
 - 24.12/2 • {AI95-00251-01} If the target type is an access-to-variable type, then the operand type shall be an access-to-variable type;
 - 24.i/2 **Ramification:** If the target type is an access-to-constant type, then the operand type can be access-to-constant or access-to-variable.
 - 24.13/2 • {AI95-00251-01} If the target designated type is tagged, then the operand designated type shall be convertible to the target designated type;

- {AI95-00251-01} {AI95-00363-01} If the target designated type is not tagged, then the designated types shall be the same, and either: 24.14/2
 - {AI95-00363-01} the designated subtypes shall statically match; or 24.15/2
 - {AI95-00363-01} {AI95-00384-01} the designated type shall be discriminated in its full view and unconstrained in any partial view, and one of the designated subtypes shall be unconstrained; 24.16/2

Ramification: {AI95-00363-01} This does not require that types have a partial view in order to allow the conversion, simply that any partial view that does exist is unconstrained. 24.j/2

{AI95-00384-01} This allows conversions both ways (either subtype can be unconstrained); while Ada 95 only allowed the conversion if the target subtype is unconstrained. We generally want type conversions to be symmetric; which type is the target shouldn't matter for legality. 24.k/2

Reason: {AI95-00363-01} If the visible partial view is constrained, we do not allow conversion between unconstrained and constrained subtypes. This means that whether the full type had discriminants is not visible to clients of the partial view. 24.l/2

Reason: These rules are designed to ensure that aliased array objects only *need* "dope" if their nominal subtype is unconstrained, but they can always *have* dope if required by the run-time model (since no sliding is permitted as part of access type conversion). By contrast, aliased discriminated objects will always *need* their discriminants stored with them, even if nominally constrained. (Here, we are assuming an implementation that represents an access value as a single pointer.) 24.m/2
- {AI95-00251-01} {AI05-0148-1} {AI05-0248-1} The accessibility level of the operand type shall not be statically deeper than that of the target type, unless the target type is an anonymous access type of a stand-alone object. If the target type is that of such a stand-alone object, the accessibility level of the operand type shall not be statically deeper than that of the declaration of the stand-alone object. In addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit. 24.17/3

Ramification: {AI05-0148-1} The access parameter case is handled by a run-time check. Run-time checks are also done in instance bodies, and for stand-alone objects of anonymous access types. 24.n/3

Reason: We prohibit storing accesses to objects deeper than a stand-alone object of an anonymous access-to-object (even while we allow storing all other accesses) in order to prevent dangling accesses. 24.n.1/3
- {AI95-00230-01} If the target type is a pool-specific access-to-object type, then the operand type shall be *universal_access*. 24.18/2

Reason: This allows **null** to be converted to pool-specific types. Without it, **null** could be converted to general access types but not pool-specific ones, which would be too inconsistent. Remember that these rules only apply to unrelated types, so we don't have to talk about conversions to derived or other related types. 24.o/2
- {AI95-00230-01} {AI95-00251-01} If the target type is an access-to-subprogram type, then the operand type shall be *universal_access* or an access-to-subprogram type. Further, if the operand type is not *universal_access*: 24.19/2
 - {AI95-00251-01} {AI05-0239-1} The designated profiles shall be subtype conformant. 24.20/3
 - {AI95-00251-01} The accessibility level of the operand type shall not be statically deeper than that of the target type. In addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit. If the operand type is declared within a generic body, the target type shall be declared within the generic body. 24.21/2

Reason: The reason it is illegal to convert from an access-to-subprogram type declared in a generic body to one declared outside that body is that in an implementation that shares generic bodies, procedures declared inside the generic need to have a different calling convention — they need an extra parameter pointing to the data declared in the current instance. For procedures declared in the spec, that's OK, because the compiler can know about them at compile time of the instantiation. 24.p/2

Static Semantics

- 25 A `type_conversion` that is a value conversion denotes the value that is the result of converting the value of the operand to the target subtype.
- 26/3 {AI05-0264-1} A `type_conversion` that is a view conversion denotes a view of the object denoted by the operand. This view is a variable of the target type if the operand denotes a variable; otherwise, it is a constant of the target type.
- 27 The nominal subtype of a `type_conversion` is its target subtype.

Dynamic Semantics

- 28 For the evaluation of a `type_conversion` that is a value conversion, the operand is evaluated, and then the value of the operand is *converted* to a *corresponding* value of the target type, if any. If there is no value of the target type that corresponds to the operand value, `Constraint_Error` is raised[; this can only happen on conversion to a modular type, and only when the operand value is outside the base range of the modular type.] Additional rules follow:
- 29 • Numeric Type Conversion
- 30 • If the target and the operand types are both integer types, then the result is the value of the target type that corresponds to the same mathematical integer as the operand.
- 31 • If the target type is a decimal fixed point type, then the result is truncated (toward 0) if the value of the operand is not a multiple of the *small* of the target type.
- 32 • If the target type is some other real type, then the result is within the accuracy of the target type (see G.2, “Numeric Performance Requirements”, for implementations that support the Numerics Annex).
- 32.a **Discussion:** An integer type might have more bits of precision than a real type, so on conversion (of a large integer), some precision might be lost.
- 33 • If the target type is an integer type and the operand type is real, the result is rounded to the nearest integer (away from zero if exactly halfway between two integers).
- 33.a/2 **Discussion:** {AI95-00267-01} This was implementation defined in Ada 83. There seems no reason to preserve the nonportability in Ada 95. Round-away-from-zero is the conventional definition of rounding, and standard Fortran and COBOL both specify rounding away from zero, so for interoperability, it seems important to pick this. This is also the most easily “undone” by hand. Round-to-nearest-even is an alternative, but that is quite complicated if not supported by the hardware. In any case, this operation is not usually part of an inner loop, so predictability and portability are judged most important. A floating point attribute function `Unbiased_Rounding` is provided (see A.5.3) for those applications that require round-to-nearest-even, and a floating point attribute function `Machine_Rounding` (also see A.5.3) is provided for those applications that require the highest possible performance. “Deterministic” rounding is required for static conversions to integer as well. See 4.9.
- 34 • Enumeration Type Conversion
- 35 • The result is the value of the target type with the same position number as that of the operand value.
- 36 • Array Type Conversion
- 37 • If the target subtype is a constrained array subtype, then a check is made that the length of each dimension of the value of the operand equals the length of the corresponding dimension of the target subtype. The bounds of the result are those of the target subtype.
- 38 • If the target subtype is an unconstrained array subtype, then the bounds of the result are obtained by converting each bound of the value of the operand to the corresponding index type of the target type. For each nonnull index range, a check is made that the bounds of the range belong to the corresponding index subtype.
- 38.a **Discussion:** Only nonnull index ranges are checked, per AI83-00313.

- In either array case, the value of each component of the result is that of the matching component of the operand value (see 4.5.2). 39
 - Ramification:** This applies whether or not the component is initialized. 39.a
- {AI95-00392-01} If the component types of the array types are anonymous access types, then a check is made that the accessibility level of the operand type is not deeper than that of the target type. 39.1/2
 - Reason:** This check is needed for operands that are access parameters and in instance bodies. Other cases are handled by the legality rule given previously. 39.b/2
- Composite (Non-Array) Type Conversion 40
 - The value of each nondiscriminant component of the result is that of the matching component of the operand value. 41
 - Ramification:** This applies whether or not the component is initialized. 41.a
 - [The tag of the result is that of the operand.] If the operand type is class-wide, a check is made that the tag of the operand identifies a (specific) type that is covered by or descended from the target type. 42
 - Ramification:** This check is certain to succeed if the operand type is itself covered by or descended from the target type. 42.a
 - Proof:** The fact that a `type_conversion` preserves the tag is stated officially in 3.9, “Tagged Types and Type Extensions” 42.b
 - For each discriminant of the target type that corresponds to a discriminant of the operand type, its value is that of the corresponding discriminant of the operand value; if it corresponds to more than one discriminant of the operand type, a check is made that all these discriminants are equal in the operand value. 43
 - For each discriminant of the target type that corresponds to a discriminant that is specified by the `derived_type_definition` for some ancestor of the operand type (or if class-wide, some ancestor of the specific type identified by the tag of the operand), its value in the result is that specified by the `derived_type_definition`. 44
 - Ramification:** It is a ramification of the rules for the discriminants of derived types that each discriminant of the result is covered either by this paragraph or the previous one. See 3.7. 44.a
 - For each discriminant of the operand type that corresponds to a discriminant that is specified by the `derived_type_definition` for some ancestor of the target type, a check is made that in the operand value it equals the value specified for it. 45
 - For each discriminant of the result, a check is made that its value belongs to its subtype. 46
- Access Type Conversion 47
 - {AI05-0148-1} {AI05-0248-1} For an access-to-object type, a check is made that the accessibility level of the operand type is not deeper than that of the target type, unless the target type is an anonymous access type of a stand-alone object. If the target type is that of such a stand-alone object, a check is made that the accessibility level of the operand type is not deeper than that of the declaration of the stand-alone object[; then if the check succeeds, the accessibility level of the target type becomes that of the operand type]. 48/3
 - Ramification:** {AI05-0148-1} This check is needed for operands that are access parameters, for stand-alone anonymous access objects, and in instance bodies. 48.a/3
 - Note that this check can never fail for the implicit conversion to the anonymous type of an access parameter that is done when calling a subprogram with an access parameter. 48.b
 - {AI95-00230-01} {AI95-00231-01} If the operand value is null, the result of the conversion is the null value of the target type. 49/2
 - Ramification:** A conversion to an anonymous access type happens implicitly as part of initializing or assigning to an anonymous access object. 49.a/2

- 50
- If the operand value is not null, then the result designates the same object (or subprogram) as is designated by the operand value, but viewed as being of the target designated subtype (or profile); any checks associated with evaluating a conversion to the target designated subtype are performed.

50.a **Ramification:** The checks are certain to succeed if the target and operand designated subtypes statically match.

51/3 {AI95-00231-01} {AI05-0153-3} {AI05-0290-1} After conversion of the value to the target type, if the target subtype is constrained, a check is performed that the value satisfies this constraint. If the target subtype excludes null, then a check is made that the value is not null. If predicate checks are enabled for the target subtype (see 3.2.4), a check is performed that the predicate of the target subtype is satisfied for the value.

51.a/2 **Ramification:** {AI95-00231-01} The first check above is a Range_Check for scalar subtypes, a Discriminant_Check or Index_Check for access subtypes, and a Discriminant_Check for discriminated subtypes. The Length_Check for an array conversion is performed as part of the conversion to the target type. The check for exclusion of null is an Access_Check.

52 For the evaluation of a view conversion, the operand name is evaluated, and a new view of the object denoted by the operand is created, whose type is the target type; if the target type is composite, checks are performed as above for a value conversion.

53 The properties of this new view are as follows:

- 54/1
- {8652/0017} {AI95-00184-01} If the target type is composite, the bounds or discriminants (if any) of the view are as defined above for a value conversion; each nondiscriminant component of the view denotes the matching component of the operand object; the subtype of the view is constrained if either the target subtype or the operand object is constrained, or if the target subtype is indefinite, or if the operand type is a descendant of the target type and has discriminants that were not inherited from the target type;
 - If the target type is tagged, then an assignment to the view assigns to the corresponding part of the object denoted by the operand; otherwise, an assignment to the view assigns to the object, after converting the assigned value to the subtype of the object (which might raise Constraint_Error);
 - Reading the value of the view yields the result of converting the value of the operand object to the target subtype (which might raise Constraint_Error), except if the object is of an access type and the view conversion is passed as an **out** parameter; in this latter case, the value of the operand object is used to initialize the formal parameter without checking against any constraint of the target subtype (see 6.4.1).

56.a **Reason:** This ensures that even an **out** parameter of an access type is initialized reasonably.

57/3 {AI05-0290-1} If an Accessibility_Check fails, Program_Error is raised. If a predicate check fails, Assertions.Assertion_Error is raised. Any other check associated with a conversion raises Constraint_Error if it fails.

58 Conversion to a type is the same as conversion to an unconstrained subtype of the type.

58.a **Reason:** This definition is needed because the semantics of various constructs involves converting to a type, whereas an explicit type_conversion actually converts to a subtype. For example, the evaluation of a range is defined to convert the values of the expressions to the type of the range.

58.b **Ramification:** A conversion to a scalar type, or, equivalently, to an unconstrained scalar subtype, can raise Constraint_Error if the value is outside the base range of the type.

NOTES

59 19 In addition to explicit type_conversions, type conversions are performed implicitly in situations where the expected type and the actual type of a construct differ, as is permitted by the type resolution rules (see 8.6). For example, an integer literal is of the type *universal_integer*, and is implicitly converted when assigned to a target of some specific integer type. Similarly, an actual parameter of a specific tagged type is implicitly converted when the corresponding formal parameter is of a class-wide type.

Even when the expected and actual types are the same, implicit subtype conversions are performed to adjust the array bounds (if any) of an operand to match the desired target subtype, or to raise `Constraint_Error` if the (possibly adjusted) value does not satisfy the constraints of the target subtype. 60

20 *{AI95-00230-01}* A ramification of the overload resolution rules is that the operand of an (explicit) `type_conversion` cannot be an `allocator`, an `aggregate`, a `string_literal`, a `character_literal`, or an `attribute_reference` for an `Access` or `Unchecked_Access` attribute. Similarly, such an expression enclosed by parentheses is not allowed. A `qualified_expression` (see 4.7) can be used instead of such a `type_conversion`. 61/2

21 The constraint of the target subtype has no effect for a `type_conversion` of an elementary type passed as an `out` parameter. Hence, it is recommended that the first subtype be specified as the target to minimize confusion (a similar recommendation applies to renaming and generic formal `in out` objects). 62

Examples

Examples of numeric type conversion: 63

```
Real (2*J)      -- value is converted to floating point 64
Integer (1.6)   -- value is 2
Integer (-0.4)  -- value is 0
```

Example of conversion between derived types: 65

```
type A_Form is new B_Form; 66
X : A_Form; 67
Y : B_Form;
X := A_Form(Y); 68
Y := B_Form(X); -- the reverse conversion
```

Examples of conversions between array types: 69

```
type Sequence is array (Integer range <>) of Integer; 70
subtype Dozen is Sequence(1 .. 12);
Ledger : array(1 .. 100) of Integer;
Sequence(Ledger) -- bounds are those of Ledger 71
Sequence(Ledger(31 .. 42)) -- bounds are 31 and 42
Dozen(Ledger(31 .. 42)) -- bounds are those of Dozen
```

Incompatibilities With Ada 83

A `character_literal` is not allowed as the operand of a `type_conversion`, since there are now two character types in package `Standard`. 71.a

The component subtypes have to statically match in an array conversion, rather than being checked for matching constraints at run time. 71.b

Because sliding of array bounds is now provided for operations where it was not in Ada 83, programs that used to raise `Constraint_Error` might now continue executing and produce a reasonable result. This is likely to fix more bugs than it creates. 71.c

Extensions to Ada 83

A `type_conversion` is considered the name of an object in certain circumstances (such a `type_conversion` is called a view conversion). In particular, as in Ada 83, a `type_conversion` can appear as an `in out` or `out` actual parameter. In addition, if the target type is tagged and the operand is the name of an object, then so is the `type_conversion`, and it can be used as the prefix to a `selected_component`, in an `object_renaming_declaration`, etc. 71.d

We no longer require type-mark conformance between a parameter of the form of a type conversion, and the corresponding formal parameter. This had caused some problems for inherited subprograms (since there isn't really a type-mark for converted formals), as well as for renamings, formal subprograms, etc. See AI83-00245, AI83-00318, AI83-00547. 71.e

We now specify “deterministic” rounding from real to integer types when the value of the operand is exactly between two integers (rounding is away from zero in this case). 71.f

“Sliding” of array bounds (which is part of conversion to an array subtype) is performed in more cases in Ada 95 than in Ada 83. Sliding is not performed on the operand of a membership test, nor on the operand of a `qualified_expression`. It wouldn't make sense on a membership test, and we wish to retain a connection between subtype membership and subtype qualification. In general, a subtype membership test returns `True` if and only if a 71.g

corresponding subtype qualification succeeds without raising an exception. Other operations that take arrays perform sliding.

Wording Changes from Ada 83

- 71.h We no longer explicitly list the kinds of things that are not allowed as the operand of a `type_conversion`, except in a NOTE.
- 71.i/3 {AI05-0299-1} The rules in this subclause subsume the rules for "parameters of the form of a type conversion," and have been generalized to cover the use of a type conversion as a name.

Incompatibilities With Ada 95

- 71.j/2 {AI95-00246-01} **Amendment Correction:** Conversions between unrelated array types that are limited or (for view conversions) might be by-reference types are now illegal. The representations of two such arrays may differ, making the conversions impossible. We make the check here, because legality should not be based on representation properties. Such conversions are likely to be rare, anyway. There is a potential that this change would make a working program illegal (if the types have the same representation).
- 71.k/2 {AI95-00363-01} If a discriminated full type has a partial view (private type) that is constrained, we do not allow conversion between access-to-unconstrained and access-to-constrained subtypes designating the type. Ada 95 allowed this conversion and the declaration of various access subtypes, requiring that the designated object be constrained and thus making details of the implementation of the private type visible to the client of the private type. See 4.8 for more on this topic.

Extensions to Ada 95

- 71.l/2 {AI95-00230-01} Conversion rules for *universal_access* were defined. These allow the use of anonymous access values in equality tests (see 4.5.2), and also allow the use of **null** in type conversions and other contexts that do not provide a single expected type.
- 71.m/2 {AI95-00384-01} A type conversion from an access-to-discriminated and unconstrained object to an access-to-discriminated and constrained one is allowed. Ada 95 only allowed the reverse conversion, which was weird and asymmetric. Of course, a constraint check will be performed for this conversion.

Wording Changes from Ada 95

- 71.n/2 {8652/0017} {AI95-00184-01} **Corrigendum:** Wording was added to ensure that view conversions are constrained, and that a tagged view conversion has a tagged object. Both rules are needed to avoid having a way to change the discriminants of a constrained object.
- 71.o/2 {8652/0008} {AI95-00168-01} **Corrigendum:** Wording was added to ensure that the aliased status of array components cannot change in a view conversion. This rule was needed to avoid having a way to change the discriminants of an aliased object. This rule was repealed later, as Ada 2005 allows changing the discriminants of an aliased object.
- 71.p/2 {AI95-00231-01} Wording was added to check subtypes that exclude null (see 3.10).
- 71.q/2 {AI95-00251-01} The organization of the legality rules was changed, both to make it clearer, and to eliminate an unintentional incompatibility with Ada 83. The old organization prevented type conversions between some types that were related by derivation (which Ada 83 always allowed).
- 71.r/3 {AI95-00330-01} {AI05-0005-1} Clarified that an untagged type conversion appearing as a generic actual parameter for a generic **in out** formal parameter is not a view conversion (and thus is illegal). This confirms the ACATS tests, so all implementations already follow this interpretation.
- 71.s/2 {AI95-00363-01} Rules added by the Corrigendum to eliminate problems with discriminants of aliased components changing were removed, as we now generally allow discriminants of aliased components to be changed.
- 71.t/2 {AI95-00392-01} Accessibility checks on conversions involving types with anonymous access components were added. These components have the level of the type, and conversions can be between types at different levels, which could cause dangling access values in the absence of such checks.

Inconsistencies With Ada 2005

- 71.u/3 {AI05-0148-1} A stand-alone object of an anonymous access-to-object type now has dynamic accessibility. Normally, this will make programs legal that were illegal in Ada 2005. However, it is possible that a program that previously raised `Program_Error` now will not. It is very unlikely that an existing program intentionally depends on the exception being raised; the change is more likely to fix bugs than introduce them.

Wording Changes from Ada 2005

- {AI05-0115-1} **Correction:** Clarified that a root numeric type is not considered a common ancestor for a conversion. 71.v/3
 {AI05-0153-3} {AI05-0290-1} Added rules so that predicate aspects (see 3.2.4) are enforced on subtype conversion. 71.w/3

4.7 Qualified Expressions

[A `qualified_expression` is used to state explicitly the type, and to verify the subtype, of an operand that is either an expression or an aggregate.] 1

Syntax

```
qualified_expression ::=
  subtype_mark'(expression) | subtype_mark'aggregate 2
```

Name Resolution Rules

The *operand* (the `expression` or `aggregate`) shall resolve to be of the type determined by the `subtype_mark`, or a universal type that covers it. 3

Static Semantics

{AI05-0003-1} [If the operand of a `qualified_expression` denotes an object, the `qualified_expression` denotes a constant view of that object.] The nominal subtype of a `qualified_expression` is the subtype denoted by the `subtype_mark`. 3.1/3

Proof: {AI05-0003-1} This is stated in 3.3. 3.a/3

Dynamic Semantics

The evaluation of a `qualified_expression` evaluates the operand (and if of a universal type, converts it to the type determined by the `subtype_mark`) and checks that its value belongs to the subtype denoted by the `subtype_mark`. The exception `Constraint_Error` is raised if this check fails. 4

Ramification: This is one of the few contexts in Ada 95 where implicit subtype conversion is not performed prior to a constraint check, and hence no “sliding” of array bounds is provided. 4.a

Reason: Implicit subtype conversion is not provided because a `qualified_expression` with a constrained target subtype is essentially an assertion about the subtype of the operand, rather than a request for conversion. An explicit `type_conversion` can be used rather than a `qualified_expression` if subtype conversion is desired. 4.b

NOTES

22 When a given context does not uniquely identify an expected type, a `qualified_expression` can be used to do so. In particular, if an overloaded `name` or `aggregate` is passed to an overloaded subprogram, it might be necessary to qualify the operand to resolve its type. 5

Examples

Examples of disambiguating expressions using qualification: 6

```
type Mask is (Fix, Dec, Exp, Signif);
type Code is (Fix, Cla, Dec, Tnz, Sub);

Print (Mask'(Dec)); -- Dec is of type Mask
Print (Code'(Dec)); -- Dec is of type Code

for J in Code'(Fix) .. Code'(Dec) loop ... -- qualification needed for either Fix or Dec
for J in Code range Fix .. Dec loop ...   -- qualification unnecessary
for J in Code'(Fix) .. Dec loop ...       -- qualification unnecessary for Dec

Dozen'(1 | 3 | 5 | 7 => 2, others => 0) -- see 4.6 10
```

Wording Changes from Ada 2005

- {AI05-0003-1} Added a definition of the nominal subtype of a `qualified_expression`. 10.a/3

4.8 Allocators

1 [The evaluation of an allocator creates an object and yields an access value that designates the object.]

Syntax

2/3 {AI05-0111-3} allocator ::=
 new [subpool_specification] subtype_indication
 | **new** [subpool_specification] qualified_expression

2.1/3 {AI05-0111-3} subpool_specification ::= (subpool_handle_name)

2.2/3 {AI05-0104-1} For an allocator with a subtype_indication, the subtype_indication shall not specify a null_exclusion.

2.a/3 **Reason:** Such an uninitialized allocator would necessarily raise Constraint_Error, as the default value is **null**. Also note that the syntax does not allow a null_exclusion in an initialized allocator, so it makes sense to make the uninitialized case illegal as well.

Name Resolution Rules

3/3 {8652/0010} {AI95-00127-01} {AI05-0111-3} {AI05-0269-1} The expected type for an allocator shall be a single access-to-object type with designated type *D* such that either *D* covers the type determined by the subtype_mark of the subtype_indication or qualified_expression, or the expected type is anonymous and the determined type is *D*'Class. A subpool_handle_name is expected to be of any type descended from Subpool_Handle, which is the type used to identify a subpool, declared in package System.Storage_Pools.Subpools (see 13.11.4).

3.a **Discussion:** See 8.6, “The Context of Overload Resolution” for the meaning of “shall be a single ... type whose ...”

3.a.1/1 **Ramification:** {8652/0010} {AI95-00127-01} An allocator is allowed as a controlling parameter of a dispatching call (see 3.9.2).

Legality Rules

4 An *initialized* allocator is an allocator with a qualified_expression. An *uninitialized* allocator is one with a subtype_indication. In the subtype_indication of an uninitialized allocator, a constraint is permitted only if the subtype_mark denotes an [unconstrained] composite subtype; if there is no constraint, then the subtype_mark shall denote a definite subtype.

4.a **Ramification:** For example, ... **new** S'Class ... (with no initialization expression) is illegal, but ... **new** S'Class(X) ... is legal, and takes its tag and constraints from the initial value X. (Note that the former case cannot have a constraint.)

5/2 {AI95-00287-01} If the type of the allocator is an access-to-constant type, the allocator shall be an initialized allocator.

5.a/2 *This paragraph was deleted.* {AI95-00287-01}

5.1/3 {AI05-0111-3} If a subpool_specification is given, the type of the storage pool of the access type shall be a descendant of Root_Storage_Pool_With_Subpools.

5.2/3 {AI95-00344-01} If the designated type of the type of the allocator is class-wide, the accessibility level of the type determined by the subtype_indication or qualified_expression shall not be statically deeper than that of the type of the allocator.

5.b/2 **Reason:** This prevents the allocated object from outliving its type.

5.3/3 {AI95-00416-01} {AI05-0051-1} If the subtype determined by the subtype_indication or qualified_expression of the allocator has one or more access discriminants, then the accessibility level of the anonymous access type of each access discriminant shall not be statically deeper than that of the type of the allocator (see 3.10.2).

- Reason:** This prevents the allocated object from outliving its discriminants. 5.c/2
- {AI95-00366-01} {AI05-0052-1} {AI05-0157-1} An allocator shall not be of an access type for which the Storage_Size has been specified by a static expression with value zero or is defined by the language to be zero. 5.4/3
- Reason:** An allocator for an access type that has Storage_Size specified to be zero is required to raise Storage_Error anyway. It's better to detect the error at compile-time, as the allocator might be executed infrequently. This also simplifies the rules for Pure units, where we do not want to allow any allocators for library-level access types, as they would represent state. 5.d/2
- {AI05-0157-1} We don't need a special rule to cover generic formals (unlike many other similar Legality Rules). There are only two cases of interest. For formal access types, the Storage_Size property is not known in the generic, and surely isn't static, so this Legality Rule can never apply. For a formal derived type, this Legality Rule can only be triggered by a parent type having one of the appropriate properties. But Storage_Size can never be specified for a derived access type, so it always has the same value for all child types; additionally, a type derived from a remote access type (which has Storage_Size defined to be zero) is also a remote access type. That means that any actual that would match the formal derived type necessarily has the same Storage_Size properties, so it is harmless (and preferable) to check them in the body - they are always known in that case. For other formal types, allocators are not allowed, so we don't need to consider them. So we don't need an assume-the-best rule here. 5.e/3
- {AI05-0052-1} If the designated type of the type of the allocator is limited, then the allocator shall not be used to define the value of an access discriminant, unless the discriminated type is immutably limited (see 7.5). 5.5/3
- Reason:** Because coextensions work very much like parts, we don't want users creating limited coextensions for nonlimited types. This would be similar to extending a nonlimited type with a limited component. We check this on the allocator. Note that there is an asymmetry in what types are considered limited; this is required to preserve privacy. We have to assume that the designated type might be limited as soon as we see a limited partial view, but we want to ensure that the containing object is of a type that is always limited. 5.f/3
- {AI05-0052-1} In addition to the places where Legality Rules normally apply (see 12.3), these rules apply also in the private part of an instance of a generic unit. 5.6/3
- Discussion:** This applies to all of the Legality Rules of this subclause. 5.g/3

Static Semantics

- {AI95-00363-01} {AI05-0041-1} If the designated type of the type of the allocator is elementary, then the subtype of the created object is the designated subtype. If the designated type is composite, then the subtype of the created object is the designated subtype when the designated subtype is constrained or there is an ancestor of the designated type that has a constrained partial view; otherwise, the created object is constrained by its initial value [(even if the designated subtype is unconstrained with defaults)]. 6/3
- Discussion:** See AI83-00331. 6.a
- Reason:** {AI95-00363-01} All objects created by an allocator are aliased, and most aliased composite objects need to be constrained so that access subtypes work reasonably. Problematic access subtypes are prohibited for types with a constrained partial view. 6.b/2
- Discussion:** {AI95-00363-01} If there is a constrained partial view of the type, this allows the objects to be unconstrained. This eliminates privacy breaking (we don't want the objects to act differently simply because they're allocated). Such a created object is effectively constrained by its initial value if the access type is an access-to-constant type, or the designated type is limited (in all views), but we don't need to state that here. It is implicit in other rules. Note, however, that a value of an access-to-constant type can designate a variable object via 'Access or conversion, and the variable object might be assigned by some other access path, and that assignment might alter the discriminants. 6.c/2

Dynamic Semantics

- {AI95-00373-01} For the evaluation of an initialized allocator, the evaluation of the qualified_expression is performed first. An object of the designated type is created and the value of the qualified_expression is converted to the designated subtype and assigned to the object. 7/2
- Ramification:** The conversion might raise Constraint_Error. 7.a

8 For the evaluation of an uninitialized allocator, the elaboration of the `subtype_indication` is performed first. Then:

- 9/2 • *{AI95-00373-01}* If the designated type is elementary, an object of the designated subtype is created and any implicit initial value is assigned;
- 10/2 • *{8652/0002}* *{AI95-00171-01}* *{AI95-00373-01}* If the designated type is composite, an object of the designated type is created with tag, if any, determined by the `subtype_mark` of the `subtype_indication`. This object is then initialized by default (see 3.3.1) using the `subtype_indication` to determine its nominal subtype. A check is made that the value of the object belongs to the designated subtype. `Constraint_Error` is raised if this check fails. This check and the initialization of the object are performed in an arbitrary order.

10.a **Discussion:** AI83-00150.

10.1/3 *{AI95-00344-01}* *{AI95-00416-01}* *{AI05-0024-1}* *{AI05-0051-1}* *{AI05-0234-1}* For any allocator, if the designated type of the type of the `allocator` is class-wide, then a check is made that the master of the type determined by the `subtype_indication`, or by the tag of the value of the `qualified_expression`, includes the elaboration of the type of the `allocator`. If any part of the subtype determined by the `subtype_indication` or `qualified_expression` of the `allocator` (or by the tag of the value if the type of the `qualified_expression` is class-wide) has one or more access discriminants, then a check is made that the accessibility level of the anonymous access type of each access discriminant is not deeper than that of the type of the `allocator`. `Program_Error` is raised if either such check fails.

10.b/3 **Reason:** *{AI95-00344-01}* *{AI05-0024-1}* The master check on class-wide types prevents the allocated object from outliving its type. We need the run-time check in instance bodies, or when the type of the `qualified_expression` is class-wide (other cases are statically detected).

10.b.1/3 *{AI05-0024-1}* We can't use the normal accessibility level “deeper than” check here because we may have “incomparable” levels if the appropriate master and the type declaration belong to two different tasks. This can happen when checking the master of the tag for an allocator initialized by a parameter passed in to an `accept` statement, if the type of the `allocator` is an access type declared in the enclosing task body. For example:

```
10.b.2/3
    task body TT is
        type Acc_TC is access T'Class;
        P : Acc_TC;
    begin
        accept E(X : T'Class) do
            P := new T'Class'(X);
            -- Master check on tag of X.
            -- Can't use "accessibility levels" since they might be incomparable.
            -- Must revert to checking that the master of the type identified by
            -- X'tag includes the elaboration of Acc_TC, so it is sure to outlive it.
        end E;
```

10.c/2 *{AI95-00416-01}* The accessibility check on access discriminants prevents the allocated object from outliving its discriminants.

10.2/2 *{AI95-00280-01}* If the object to be created by an `allocator` has a controlled or protected part, and the finalization of the collection of the type of the `allocator` (see 7.6.1) has started, `Program_Error` is raised.

10.d/2 **Reason:** If the object has a controlled or protected part, its finalization is likely to be nontrivial. If the allocation was allowed, we could not know whether the finalization would actually be performed. That would be dangerous to otherwise safe abstractions, so we mandate a check here. On the other hand, if the finalization of the object will be trivial, we do not require (but allow) the check, as no real harm could come from late allocation.

10.e/2 **Discussion:** This check can only fail if an `allocator` is evaluated in code reached from a `Finalize` routine for a type declared in the same master. That's highly unlikely; `Finalize` routines are much more likely to be deallocating objects than allocating them.

10.3/2 *{AI95-00280-01}* If the object to be created by an `allocator` contains any tasks, and the master of the type of the `allocator` is completed, and all of the dependent tasks of the master are terminated (see 9.3), then `Program_Error` is raised.

10.f/2 **Reason:** A task created after waiting for tasks has finished could depend on freed data structures, and certainly would never be awaited.

{AI05-0111-3} If the `allocator` includes a `subpool_handle_name`, `Constraint_Error` is raised if the subpool handle is `null`. `Program_Error` is raised if the subpool does not *belong* (see 13.11.4) to the storage pool of the access type of the `allocator`. 10.4/3

Implementation Note: This can be implemented by comparing the result of `Pool_of_Subpool` to a reference to the storage pool object. `Pool_of_Subpool`'s parameter is **not null**, so the check for null falls out naturally. 10.g/3

Reason: This detects cases where the subpool belongs to another pool, or to no pool at all. This includes detecting dangling subpool handles so long as the subpool object (the object designated by the handle) still exists. (If the subpool object has been deallocated, execution is erroneous; it is likely that this check will still detect the problem, but there cannot be a guarantee.) 10.h/3

[If the created object contains any tasks, they are activated (see 9.2).] Finally, an access value that designates the created object is returned. 11

Bounded (Run-Time) Errors

{AI95-00280-01} It is a bounded error if the finalization of the collection of the type (see 7.6.1) of the `allocator` has started. If the error is detected, `Program_Error` is raised. Otherwise, the allocation proceeds normally. 11.1/2

Discussion: This check is required in some cases; see above. 11.a/2

NOTES

23 Allocators cannot create objects of an abstract type. See 3.9.3. 12

24 If any part of the created object is controlled, the initialization includes calls on corresponding `Initialize` or `Adjust` procedures. See 7.6. 13

25 As explained in 13.11, “Storage Management”, the storage for an object allocated by an `allocator` comes from a storage pool (possibly user defined). The exception `Storage_Error` is raised by an `allocator` if there is not enough storage. Instances of `Unchecked_Deallocation` may be used to explicitly reclaim storage. 14

26 {AI05-0229-1} Implementations are permitted, but not required, to provide garbage collection. 15/3

Ramification: Note that in an `allocator`, the exception `Constraint_Error` can be raised by the evaluation of the `qualified_expression`, by the elaboration of the `subtype_indication`, or by the initialization. 15.a

Discussion: By default, the implementation provides the storage pool. The user may exercise more control over storage management by associating a user-defined pool with an access type. 15.b

Examples

Examples of allocators: 16

```
new Cell'(0, null, null) -- initialized explicitly, see 3.10.1 17
new Cell'(Value => 0, Succ => null, Pred => null) -- initialized explicitly
new Cell -- not initialized
new Matrix(1 .. 10, 1 .. 20) -- the bounds only are given 18
new Matrix'(1 .. 10 => (1 .. 20 => 0.0)) -- initialized explicitly
new Buffer(100) -- the discriminant only is given 19
new Buffer'(Size => 80, Pos => 0, Value => (1 .. 80 => 'A')) -- initialized explicitly
Expr_Ptr'(new Literal) -- allocator for access-to-class-wide type, see 3.9.1 20
Expr_Ptr'(new Literal'(Expression with 3.5)) -- initialized explicitly
```

Incompatibilities With Ada 83

The `subtype_indication` of an uninitialized `allocator` may not have an explicit `constraint` if the designated type is an access type. In Ada 83, this was permitted even though the `constraint` had no effect on the subtype of the created object. 20.a/1

Extensions to Ada 83

Allocators creating objects of type *T* are now overloaded on access types designating *T*Class and all class-wide types that cover *T*. 20.b

Implicit array subtype conversion (sliding) is now performed as part of an initialized `allocator`. 20.c

Wording Changes from Ada 83

- 20.d We have used a new organization, inspired by the ACID document, that makes it clearer what is the subtype of the created object, and what subtype conversions take place.
- 20.e Discussion of storage management issues, such as garbage collection and the raising of `Storage_Error`, has been moved to 13.11, “Storage Management”.

Inconsistencies With Ada 95

- 20.f/2 *{AI95-00363-01}* If the designated type has a constrained partial view, the allocated object can be unconstrained. This might cause the object to take up a different amount of memory, and might cause the operations to work where they previously would have raised `Constraint_Error`. It's unlikely that the latter would actually matter in a real program (`Constraint_Error` usually indicates a bug that would be fixed, not left in a program.) The former might cause `Storage_Error` to be raised at a different time than in an Ada 95 program.

Incompatibilities With Ada 95

- 20.g/2 *{AI95-00366-01}* An allocator for an access type that has `Storage_Size` specified to be zero is now illegal. Ada 95 allowed the allocator, but it had to raise `Storage_Error` if executed. The primary impact of this change should be to detect bugs.

Extensions to Ada 95

- 20.h/2 *{8652/0010}* *{AI95-00127-01}* **Corrigendum:** An allocator can be a controlling parameter of a dispatching call. This was an oversight in Ada 95.
- 20.i/2 *{AI95-00287-01}* Initialized allocators are allowed when the designated type is limited.

Wording Changes from Ada 95

- 20.j/2 *{8652/0002}* *{AI95-00171-01}* **Corrigendum:** Clarified the elaboration of per-object constraints for an uninitialized allocator.
- 20.k/2 *{AI95-00280-01}* `Program_Error` is now raised if the allocator occurs after the finalization of the collection or the waiting for tasks. This is not listed as an incompatibility as the Ada 95 behavior was unspecified, and Ada 95 implementations tend to generate programs that crash in this case.
- 20.l/2 *{AI95-00344-01}* Added accessibility checks to class-wide allocators. These checks could not fail in Ada 95 (as all of the designated types had to be declared at the same level, so the access type would necessarily have been at the same level or more nested than the type of allocated object).
- 20.m/2 *{AI95-00373-01}* Revised the description of evaluation of uninitialized allocators to use “initialized by default” so that the ordering requirements are the same for all kinds of objects that are default-initialized.
- 20.n/2 *{AI95-00416-01}* Added accessibility checks to access discriminants of allocators. These checks could not fail in Ada 95 as the discriminants always have the accessibility of the object.

Incompatibilities With Ada 2005

- 20.o/3 *{AI05-0052-1}* **Correction:** Added a rule to prevent limited coextensions of nonlimited types. Allowing this would have far-reaching implementation costs. Because of those costs, it seems unlikely that any implementation ever supported it properly and thus it is unlikely that any existing code depends on this capability.
- 20.p/3 *{AI05-0104-1}* **Correction:** Added a rule to make `null_exclusions` illegal for uninitialized allocators, as such an allocator would always raise `Constraint_Error`. Programs that depend on the unconditional raising of a predefined exception should be very rare.

Extensions to Ada 2005

- 20.q/3 *{AI05-0111-3}* Subpool handles (see 13.11.4) can be specified in an allocator.

Wording Changes from Ada 2005

- 20.r/3 *{AI05-0024-1}* **Correction:** Corrected the master check for tags since the masters may be for different tasks and thus incomparable.
- 20.s/3 *{AI05-0041-1}* **Correction:** Corrected the rules for when a designated object is constrained by its initial value so that types derived from a partial view are handled properly.
- 20.t/3 *{AI05-0051-1}* *{AI05-0234-1}* **Correction:** Corrected the accessibility check for access discriminants so that it does not depend on the designated type (which might not have discriminants when the allocated type does).

4.9 Static Expressions and Static Subtypes

Certain expressions of a scalar or string type are defined to be static. Similarly, certain discrete ranges are defined to be static, and certain scalar and string subtypes are defined to be static subtypes. [*Static* means determinable at compile time, using the declared properties or values of the program entities.]

Discussion: As opposed to more elaborate data flow analysis, etc.

Language Design Principles

For an expression to be static, it has to be calculable at compile time.

Only scalar and string expressions are static.

To be static, an expression cannot have any nonscalar, nonstring subexpressions (though it can have nonscalar constituent names). A static scalar expression cannot have any nonscalar subexpressions. There is one exception — a membership test for a string subtype can be static, and the result is scalar, even though a subexpression is nonscalar.

The rules for evaluating static expressions are designed to maximize portability of static calculations.

A static expression is [a scalar or string expression that is] one of the following:

- a `numeric_literal`;
 - Ramification:** A `numeric_literal` is always a static expression, even if its expected type is not that of a static subtype. However, if its value is explicitly converted to, or qualified by, a nonstatic subtype, the resulting expression is nonstatic.
- a `string_literal` of a static string subtype;
 - Ramification:** That is, the constrained subtype defined by the index range of the string is static. Note that elementary values don't generally have subtypes, while composite values do (since the bounds or discriminants are inherent in the value).
- a `name` that denotes the declaration of a named number or a static constant;
 - Ramification:** Note that enumeration literals are covered by the `function_call` case.
- a `function_call` whose `function_name` or `function_prefix` statically denotes a static function, and whose actual parameters, if any (whether given explicitly or by default), are all static expressions;
 - Ramification:** This includes uses of operators that are equivalent to `function_calls`.
- an `attribute_reference` that denotes a scalar value, and whose `prefix` denotes a static scalar subtype;
 - Ramification:** Note that this does not include the case of an attribute that is a function; a reference to such an attribute is not even an expression. See above for `function_calls`.
 - An implementation may define the staticness and other properties of implementation-defined attributes.
- an `attribute_reference` whose `prefix` statically denotes a statically constrained array object or array subtype, and whose `attribute_designator` is `First`, `Last`, or `Length`, with an optional dimension;
- a `type_conversion` whose `subtype_mark` denotes a static scalar subtype, and whose operand is a static expression;
- a `qualified_expression` whose `subtype_mark` denotes a static [(scalar or string)] subtype, and whose operand is a static expression;
 - Ramification:** This rules out the `subtype_mark'aggregate` case.
 - Reason:** Adding qualification to an expression shouldn't make it nonstatic, even for strings.
- `{AI05-0158-1}` `{AI05-0269-1}` a membership test whose `simple_expression` is a static expression, and whose `membership_choice_list` consists only of `membership_choices` that are either `static_choice_expressions`, `static_ranges`, or `subtype_marks` that denote a static [(scalar or string)] subtype;

- 11.a **Reason:** Clearly, we should allow membership tests in exactly the same cases where we allow `qualified_expressions`.
- 12 • a short-circuit control form both of whose relations are static expressions;
- 12.1/3 • `{AI05-0147-1}` `{AI05-0188-1}` a `conditional_expression` all of whose conditions, `selecting_expressions`, and `dependent_expressions` are static expressions;
- 13 • a static expression enclosed in parentheses.
- 13.a **Discussion:** Informally, we talk about a *static value*. When we do, we mean a value specified by a static expression.
- 13.b **Ramification:** The language requires a static expression in a `number_declaration`, a numeric type definition, a `discrete_choice` (sometimes), certain representation items, an `attribute_designator`, and when specifying the value of a discriminant governing a `variant_part` in a `record_aggregate` or `extension_aggregate`.
- 14 A name *statically denotes* an entity if it denotes the entity and:
- 15 • It is a `direct_name`, expanded name, or `character_literal`, and it denotes a declaration other than a `renaming_declaration`; or
- 16 • It is an `attribute_reference` whose `prefix` statically denotes some entity; or
- 17 • It denotes a `renaming_declaration` with a name that statically denotes the renamed entity.
- 17.a **Ramification:** Selected `components` that are not expanded names and `indexed_components` do not statically denote things.
- 18 A *static function* is one of the following:
- 18.a **Ramification:** These are the functions whose calls can be static expressions.
- 19 • a predefined operator whose parameter and result types are all scalar types none of which are descendants of formal scalar types;
- 20 • a predefined concatenation operator whose result type is a string type;
- 21 • an enumeration literal;
- 22 • a language-defined attribute that is a function, if the `prefix` denotes a static scalar subtype, and if the parameter and result types are scalar.
- 23 In any case, a generic formal subprogram is not a static function.
- 24 A *static constant* is a constant view declared by a full constant declaration or an `object_renaming_declaration` with a static nominal subtype, having a value defined by a static scalar expression or by a static string expression whose value has a length not exceeding the maximum length of a `string_literal` in the implementation.
- 24.a **Ramification:** A deferred constant is not static; the view introduced by the corresponding full constant declaration can be static.
- 24.b/3 **Reason:** `{AI05-0229-1}` The reason for restricting the length of static string constants is so that compilers don't have to store giant strings in their symbol tables. Since most string constants will be initialized from `string_literals`, the length limit seems pretty natural. The reason for avoiding nonstring types is also to save symbol table space. We're trying to keep it cheap and simple (from the implementer's viewpoint), while still allowing, for example, the `aspect_definition` for a `Link_Name` aspect to contain a concatenation.
- 24.c The length we're talking about is the maximum number of characters in the value represented by a `string_literal`, not the number of characters in the source representation; the quotes don't count.
- 25 A *static range* is a `range` whose bounds are static expressions, [or a `range_attribute_reference` that is equivalent to such a `range`.] A *static discrete range* is one that is a static range or is a `subtype_indication` that defines a static scalar subtype. The base range of a scalar type is a static range, unless the type is a descendant of a formal scalar type.
- 26/3 `{AI95-00263-01}` `{AI05-0153-3}` A *static subtype* is either a *static scalar subtype* or a *static string subtype*. A static scalar subtype is an unconstrained scalar subtype whose type is not a descendant of a formal type, or a constrained scalar subtype formed by imposing a compatible static constraint on a static

scalar subtype. A static string subtype is an unconstrained string subtype whose index subtype and component subtype are static, or a constrained string subtype formed by imposing a compatible static constraint on a static string subtype. In any case, the subtype of a generic formal object of mode **in out**, and the result subtype of a generic formal function, are not static. Also, a subtype is not static if any `Dynamic_Predicate` specifications apply to it.

Ramification: String subtypes are the only composite subtypes that can be static. 26.a

Reason: The part about generic formal objects of mode **in out** is necessary because the subtype of the formal is not required to have anything to do with the subtype of the actual. For example: 26.b

```
subtype Int10 is Integer range 1..10; 26.c
```

```
generic 26.d
```

```
  F : in out Int10;
```

```
procedure G;
```

```
procedure G is
```

```
begin
```

```
  case F is
```

```
    when 1..10 => null;
```

```
    -- Illegal!
```

```
  end case;
```

```
end G;
```

```
X : Integer range 1..20; 26.f
```

```
procedure I is new G(F => X); -- OK.
```

The `case_statement` is illegal, because the subtype of `F` is not static, so the choices have to cover all values of `Integer`, not just those in the range `1..10`. A similar issue arises for generic formal functions, now that function calls are object names. 26.g

The different kinds of *static constraint* are defined as follows: 27

- A null constraint is always static; 28
- A scalar constraint is static if it has no `range_constraint`, or one with a static range; 29
- An index constraint is static if each `discrete_range` is static, and each index subtype of the corresponding array type is static; 30
- A discriminant constraint is static if each `expression` of the constraint is static, and the subtype of each discriminant is static. 31

{AI95-00311-01} In any case, the constraint of the first subtype of a scalar formal type is neither static nor null. 31.1/2

A subtype is *statically constrained* if it is constrained, and its constraint is static. An object is *statically constrained* if its nominal subtype is statically constrained, or if it is a static string constant. 32

Legality Rules

{AI05-0147-1} An expression is *statically unevaluated* if it is part of: 32.1/3

- {AI05-0147-1} the right operand of a static short-circuit control form whose value is determined by its left operand; or 32.2/3
- {AI05-0147-1} {AI05-0188-1} a *dependent_expression* of an *if_expression* whose associated condition is static and equals `False`; or 32.3/3
- {AI05-0147-1} {AI05-0188-1} a condition or *dependent_expression* of an *if_expression* where the condition corresponding to at least one preceding *dependent_expression* of the *if_expression* is static and equals `True`; or 32.4/3

Reason: We need this bullet so that only a single *dependent_expression* is evaluated in a static *if_expression* if there is more than one condition that evaluates to `True`. The part about conditions makes 32.a/3

```
(if N = 0 then Min elsif 10_000/N > Min then 10_000/N else Min) 32.b/3
```

legal if `N` and `Min` are static and `N = 0`. 32.c/3

- 32.d/3 **Discussion:** *{AI05-0147-1} {AI05-0188-1}* We need the "of the `if_expression`" here so there is no confusion for nested `if_expressions`; this rule only applies to the conditions and *dependent_expressions* of a single `if_expression`. Similar reasoning applies to the "of a `case_expression`" of the last bullet.
- 32.5/3 • *{AI05-0188-1} {AI05-0269-1}* a *dependent_expression* of a `case_expression` whose *selecting_expression* is static and whose value is not covered by the corresponding `discrete_choice_list`; or
- 32.6/3 • *{AI05-0158-1}* a `choice_expression` (or a `simple_expression` of a range that occurs as a `membership_choice` of a `membership_choice_list`) of a static membership test that is preceded in the enclosing `membership_choice_list` by another item whose individual membership test (see 4.5.2) statically yields True.
- 33/3 *{AI05-0147-1}* A static expression is evaluated at compile time except when it is statically unevaluated. The compile-time evaluation of a static expression is performed exactly, without performing `Overflow_Checks`. For a static expression that is evaluated:
- 34/3 • *{AI05-0262-1}* The expression is illegal if its evaluation fails a language-defined check other than `Overflow_Check`. For the purposes of this evaluation, the assertion policy is assumed to be `Check`.
- 34.a/3 **Reason:** *{AI05-0262-1}* Assertion policies can control whether checks are made, but we don't want assertion policies to affect legality. For Ada 2012, subtype predicates are the only checks controlled by the assertion policy that can appear in static expressions.
- 35/2 • *{AI95-00269-01}* If the expression is not part of a larger static expression and the expression is expected to be of a single specific type, then its value shall be within the base range of its expected type. Otherwise, the value may be arbitrarily large or small.
- 35.a/2 **Ramification:** *{AI95-00269-01}* If the expression is expected to be of a universal type, or of "any integer type", there are no limits on the value of the expression.
- 36/2 • *{AI95-00269-01}* If the expression is of type *universal_real* and its expected type is a decimal fixed point type, then its value shall be a multiple of the *small* of the decimal type. This restriction does not apply if the expected type is a descendant of a formal scalar type (or a corresponding actual type in an instance).
- 36.a **Ramification:** This means that a `numeric_literal` for a decimal type cannot have "extra" significant digits.
- 36.b/2 **Reason:** *{AI95-00269-01}* The *small* is not known for a generic formal type, so we have to exclude formal types from this check.
- 37/2 *{AI95-00269-01}* In addition to the places where Legality Rules normally apply (see 12.3), the above restrictions also apply in the private part of an instance of a generic unit.
- 37.a **Discussion:** Values outside the base range are not permitted when crossing from the "static" domain to the "dynamic" domain. This rule is designed to enhance portability of programs containing static expressions. Note that this rule applies to the exact value, not the value after any rounding or truncation. (See below for the rounding and truncation requirements.)
- 37.b Short-circuit control forms are a special case:
- 37.c N: `constant := 0.0;`
X: `constant Boolean := (N = 0.0) or else (1.0/N > 0.5); -- Static.`
- 37.d The declaration of X is legal, since the divide-by-zero part of the expression is not evaluated. X is a static constant equal to True.

Implementation Requirements

- 38/2 *{AI95-00268-01} {AI95-00269-01}* For a real static expression that is not part of a larger static expression, and whose expected type is not a descendant of a formal type, the implementation shall round or truncate the value (according to the `Machine_Rounds` attribute of the expected type) to the nearest machine number of the expected type; if the value is exactly half-way between two machine numbers, the rounding performed is implementation-defined. If the expected type is a descendant of a formal type, or if the static expression appears in the body of an instance of a generic unit and the corresponding expression

Extensions to Ada 83

- 44.a The rules for static expressions and static subtypes are generalized to allow more kinds of compile-time-known expressions to be used where compile-time-known values are required, as follows:
- 44.b
- Membership tests and short-circuit control forms may appear in a static expression.
- 44.c
- The bounds and length of statically constrained array objects or subtypes are static.
- 44.d
- The Range attribute of a statically constrained array subtype or object gives a static range.
- 44.e
- A `type_conversion` is static if the `subtype_mark` denotes a static scalar subtype and the operand is a static expression.
- 44.f
- All numeric literals are now static, even if the expected type is a formal scalar type. This is useful in `case_statements` and `variant_parts`, which both now allow a value of a formal scalar type to control the selection, to ease conversion of a package into a generic package. Similarly, named array aggregates are also permitted for array types with an index type that is a formal scalar type.
- 44.g The rules for the evaluation of static expressions are revised to require exact evaluation at compile time, and force a machine number result when crossing from the static realm to the dynamic realm, to enhance portability and predictability. Exact evaluation is not required for descendants of a formal scalar type, to simplify generic code sharing and to avoid generic contract model problems.
- 44.h Static expressions are legal even if an intermediate in the expression goes outside the base range of the type. Therefore, the following will succeed in Ada 95, whereas it might raise an exception in Ada 83:
- 44.i
- ```
type Short_Int is range -32_768 .. 32_767;
I : Short_Int := -32_768;
```
- 44.j This might raise an exception in Ada 83 because "32\_768" is out of range, even though "-32\_768" is not. In Ada 95, this will always succeed.
- 44.k Certain expressions involving string operations (in particular concatenation and membership tests) are considered static in Ada 95.
- 44.l The reason for this change is to simplify the rule requiring compile-time-known string expressions as the link name in an interfacing pragma, and to simplify the preelaborability rules.

*Incompatibilities With Ada 83*

- 44.m An Ada 83 program that uses an out-of-range static value is illegal in Ada 95, unless the expression is part of a larger static expression, or the expression is not evaluated due to being on the right-hand side of a short-circuit control form.

*Wording Changes from Ada 83*

- 44.n/3 {AI05-0299-1} This subclause (and 4.5.5, "Multiplying Operators") subsumes the RM83 section on Universal Expressions.
- 44.o The existence of static string expressions necessitated changing the definition of static subtype to include string subtypes. Most occurrences of "static subtype" have been changed to "static scalar subtype", in order to preserve the effect of the Ada 83 rules. This has the added benefit of clarifying the difference between "static subtype" and "statically constrained subtype", which has been a source of confusion. In cases where we allow static string subtypes, we explicitly use phrases like "static string subtype" or "static (scalar or string) subtype", in order to clarify the meaning for those who have gotten used to the Ada 83 terminology.
- 44.p In Ada 83, an expression was considered nonstatic if it raised an exception. Thus, for example:
- 44.q
- ```
Bad: constant := 1/0; -- Illegal!
```
- 44.r was illegal because 1/0 was not static. In Ada 95, the above example is still illegal, but for a different reason: 1/0 is static, but there's a separate rule forbidding the exception raising.

Inconsistencies With Ada 95

- 44.s/2 {AI95-00268-01} **Amendment Correction:** Rounding of static real expressions is implementation-defined in Ada 2005, while it was specified as away from zero in (original) Ada 95. This could make subtle differences in programs. However, the original Ada 95 rule required rounding that (probably) differed from the target processor, thus creating anomalies where the value of a static expression was required to be different than the same expression evaluated at run-time.

Wording Changes from Ada 95

- 44.t/2 {AI95-00263-01} {AI95-00268-01} The Ada 95 wording that defined static subtypes unintentionally failed to exclude formal derived types that happen to be scalar (these aren't formal scalar types); and had a parenthetical remark

excluding formal string types - but that was neither necessary nor parenthetical (it didn't follow from other wording). This issue also applies to the rounding rules for real static expressions.

{AI95-00269-01} Ada 95 didn't clearly define the bounds of a value of a static expression for universal types and for "any integer/float/fixed type". We also make it clear that we do not intend exact evaluation of static expressions in an instance body if the expressions aren't static in the generic body. 44.u/2

{AI95-00311-01} We clarify that the first subtype of a scalar formal type has a nonstatic, nonnull constraint. 44.v/2

Wording Changes from Ada 2005

{AI05-0147-1} {AI05-0188-1} Added wording to define staticness and the lack of evaluation for `if_expressions` and `case_expressions`. These are new and defined elsewhere. 44.w/3

{AI05-0153-3} Added wording to prevent subtypes that have dynamic predicates (see 3.2.4) from being static. 44.x/3

{AI05-0158-1} Revised wording for membership tests to allow for the new possibilities allowed by the `membership_choice_list`. 44.y/3

4.9.1 Statically Matching Constraints and Subtypes

Static Semantics

{AI95-00311-01} A constraint *statically matches* another constraint if: 1/2

- both are null constraints; 1.1/2
- both are static and have equal corresponding bounds or discriminant values; 1.2/2
- both are nonstatic and result from the same elaboration of a constraint of a `subtype_indication` or the same evaluation of a `range` of a `discrete_subtype_definition`; or 1.3/2
- {AI95-00311-01} both are nonstatic and come from the same `formal_type_declaration`. 1.4/2

{AI95-00231-01} {AI95-00254-01} {AI05-0153-3} A subtype *statically matches* another subtype of the same type if they have statically matching constraints, all predicate specifications that apply to them come from the same declarations, and, for access subtypes, either both or neither exclude null. Two anonymous access-to-object subtypes statically match if their designated subtypes statically match, and either both or neither exclude null, and either both or neither are access-to-constant. Two anonymous access-to-subprogram subtypes statically match if their designated profiles are subtype conformant, and either both or neither exclude null. 2/3

Ramification: Statically matching constraints and subtypes are the basis for subtype conformance of profiles (see 6.3.1). 2.a

Reason: Even though anonymous access types always represent different types, they can statically match. That's important so that they can be used widely. For instance, if this wasn't true, access parameters and access discriminants could never conform, so they couldn't be used in separate specifications. 2.b/2

Two ranges of the same type *statically match* if both result from the same evaluation of a `range`, or if both are static and have equal corresponding bounds. 3

Ramification: The notion of static matching of ranges is used in 12.5.3, "Formal Array Types"; the index ranges of formal and actual constrained array subtypes have to statically match. 3.a

{AI05-0086-1} {AI05-0153-3} A constraint is *statically compatible* with a scalar subtype if it statically matches the constraint of the subtype, or if both are static and the constraint is compatible with the subtype. A constraint is *statically compatible* with an access or composite subtype if it statically matches the constraint of the subtype, or if the subtype is unconstrained. 4/3

Discussion: Static compatibility is required when constraining a parent subtype with a discriminant from a new `discriminant_part`. See 3.7. Static compatibility is also used in matching generic formal derived types. 4.a

Note that statically compatible with a subtype does not imply compatible with a type. It is OK since the terms are used in different contexts. 4.b

- 5/3 {AI05-0153-3} Two statically matching subtypes are statically compatible with each other. In addition, a subtype *S1* is statically compatible with a subtype *S2* if:
- 6/3 • the constraint of *S1* is statically compatible with *S2*, and
 - 7/3 • {AI05-0086-1} if *S2* excludes null, so does *S1*, and
 - 8/3 • either:
 - 9/3 • all predicate specifications that apply to *S2* apply also to *S1*, or
 - 10/3 • both subtypes are static, every value that satisfies the predicate of *S1* also satisfies the predicate of *S2*, and it is not the case that both types each have at least one applicable predicate specification, predicate checks are enabled (see 11.4.2) for *S2*, and predicate checks are not enabled for *S1*.

Wording Changes from Ada 83

- 10.a This subclause is new to Ada 95.

Wording Changes from Ada 95

- 10.b/2 {AI95-00231-01} {AI95-00254-01} Added static matching rules for null exclusions and anonymous access-to-subprogram types; both of these are new.

- 10.c/2 {AI95-00311-01} We clarify that the constraint of the first subtype of a scalar formal type statically matches itself.

Incompatibilities With Ada 2005

- 10.d/3 {AI05-0086-1} **Correction:** Updated the statically compatible rules to take null exclusions into account. This is technically incompatible, as it could cause a legal Ada 2005 program to be rejected; however, such a program violates the intent of the rules (for instance, 3.7(15)) and this probably will simply detect bugs.

Wording Changes from Ada 2005

- 10.e/3 {AI05-0153-3} {AI05-0290-1} Modified static matching and static compatibility to take predicate aspects (see 3.2.4) into account.

5 Statements

[A statement defines an action to be performed upon its execution.] 1

{AI95-00318-02} {AI05-0299-1} [This clause describes the general rules applicable to all statements. Some statements are discussed in later clauses: Procedure_call_statements and return statements are described in 6, “Subprograms”. Entry_call_statements, requeue_statements, delay_statements, accept_statements, select_statements, and abort_statements are described in 9, “Tasks and Synchronization”. Raise_statements are described in 11, “Exceptions”, and code_statements in 13. The remaining forms of statements are presented in this clause.] 2/3

Wording Changes from Ada 83

{AI95-00318-02} The description of return statements has been moved to 6.5, “Return Statements”, so that it is closer to the description of subprograms. 2.a/2

5.1 Simple and Compound Statements - Sequences of Statements

[A statement is either simple or compound. A simple_statement encloses no other statement. A compound_statement can enclose simple_statements and other compound_statements.] 1

Syntax

{AI05-0179-1} sequence_of_statements ::= statement {statement} {label} 2/3

statement ::= 3
 {label} simple_statement | {label} compound_statement

{AI95-00318-02} simple_statement ::= null_statement 4/2
 | assignment_statement | exit_statement
 | goto_statement | procedure_call_statement
 | simple_return_statement | entry_call_statement
 | requeue_statement | delay_statement
 | abort_statement | raise_statement
 | code_statement

{AI95-00318-02} compound_statement ::= 5/2
 if_statement | case_statement
 | loop_statement | block_statement
 | extended_return_statement
 | accept_statement | select_statement

null_statement ::= null; 6

label ::= <<label_statement_identifier>> 7

statement_identifier ::= direct_name 8

The direct_name of a statement_identifier shall be an identifier (not an operator_symbol). 9

Name Resolution Rules

The direct_name of a statement_identifier shall resolve to denote its corresponding implicit declaration (see below). 10

Legality Rules

Distinct identifiers shall be used for all statement_identifiers that appear in the same body, including inner block_statements but excluding inner program units. 11

Static Semantics

- 12 For each `statement_identifier`, there is an implicit declaration (with the specified identifier) at the end of the `declarative_part` of the innermost `block_statement` or body that encloses the `statement_identifier`. The implicit declarations occur in the same order as the `statement_identifiers` occur in the source text. If a usage name denotes such an implicit declaration, the entity it denotes is the `label`, `loop_statement`, or `block_statement` with the given `statement_identifier`.
- 12.a **Reason:** We talk in terms of individual `statement_identifiers` here rather than in terms of the corresponding statements, since a given statement may have multiple `statement_identifiers`.
- 12.b A `block_statement` that has no explicit `declarative_part` has an implicit empty `declarative_part`, so this rule can safely refer to the `declarative_part` of a `block_statement`.
- 12.c The scope of a declaration starts at the place of the declaration itself (see 8.2). In the case of a label, loop, or block name, it follows from this rule that the scope of the implicit declaration starts before the first explicit occurrence of the corresponding name, since this occurrence is either in a statement label, a `loop_statement`, a `block_statement`, or a `goto_statement`. An implicit declaration in a `block_statement` may hide a declaration given in an outer program unit or `block_statement` (according to the usual rules of hiding explained in 8.3).
- 12.d The syntax rule for `label` uses `statement_identifier` which is a `direct_name` (not a `defining_identifier`), because labels are implicitly declared. The same applies to loop and block names. In other words, the `label` itself is not the defining occurrence; the implicit declaration is.
- 12.e We cannot consider the `label` to be a defining occurrence. An example that can tell the difference is this:
- 12.f
- ```

declare
 -- Label Foo is implicitly declared here.
begin
 for Foo in ... loop
 ...
 <<Foo>> -- Illegal.
 ...
 end loop;
end;

```
- 12.g/3 {AI05-0299-1} The label in this example is hidden from itself by the loop parameter with the same name; the example is illegal. We considered creating a new syntactic category name, separate from `direct_name` and `selector_name`, for use in the case of statement labels. However, that would confuse the rules in Clause 8, so we didn't do it.
- 12.1/3 {AI05-0179-1} If one or more labels end a `sequence_of_statements`, an implicit `null_statement` follows the labels before any following constructs.
- 12.g.1/3 **Reason:** The semantics of a `goto_statement` is defined in terms of the statement having (following) that label. Thus we ensure that every label has a following statement, which might be implicit.

*Dynamic Semantics*

- 13 The execution of a `null_statement` has no effect.
- 14/2 {AI95-00318-02} A *transfer of control* is the run-time action of an `exit_statement`, return statement, `goto_statement`, or `requeue_statement`, selection of a `terminate_alternative`, raising of an exception, or an abort, which causes the next action performed to be one other than what would normally be expected from the other rules of the language. [As explained in 7.6.1, a transfer of control can cause the execution of constructs to be completed and then left, which may trigger finalization.]
- 15 The execution of a `sequence_of_statements` consists of the execution of the individual statements in succession until the `sequence_` is completed.
- 15.a **Ramification:** It could be completed by reaching the end of it, or by a transfer of control.
- NOTES
- 16 1 A `statement_identifier` that appears immediately within the declarative region of a named `loop_statement` or an `accept_statement` is nevertheless implicitly declared immediately within the declarative region of the innermost enclosing body or `block_statement`; in other words, the expanded name for a named statement is not affected by whether the statement occurs inside or outside a named loop or an `accept_statement` — only nesting within `block_statements` is relevant to the form of its expanded name.

**Discussion:** Each comment in the following example gives the expanded name associated with an entity declared in the task body: 16.a

```

task body Compute is
 Sum : Integer := 0;
begin
 Outer:
 for I in 1..10 loop
 Blk:
 declare
 Sum : Integer := 0;
 begin
 accept Ent(I : out Integer; J : in Integer) do
 Compute.Ent.I := Compute.Outer.I;
 Inner:
 for J in 1..10 loop
 Sum := Sum + Compute.Blk.Inner.J * Compute.Ent.J;
 end loop Inner;
 end Ent;
 Compute.Sum := Compute.Sum + Compute.Blk.Sum;
 end Blk;
 end loop Outer;
 Record_Result(Sum);
end Compute;

```

#### Examples

*Examples of labeled statements:*

```

<<Here>> <<Ici>> <<Aqui>> <<Hier>> null;
<<After>> X := 1;

```

#### Extensions to Ada 83

The `requeue_statement` is new. 19.a

#### Wording Changes from Ada 83

We define the syntactic category `statement_identifier` to simplify the description. It is used for labels, loop names, and block names. We define the entity associated with the implicit declarations of statement names. 19.b

Completion includes completion caused by a transfer of control, although RM83-5.1(6) did not take this view. 19.c

#### Extensions to Ada 95

{AI95-00318-02} The `extended_return_statement` is new (`simple_return_statement` is merely renamed). 19.d/2

#### Extensions to Ada 2005

{AI95-0179-1} A label can end a `sequence_of_statements`, eliminating the requirement for having an explicit `null`; statement after an ending label (a common use). 19.e/3

## 5.2 Assignment Statements

[An `assignment_statement` replaces the current value of a variable with the result of evaluating an expression.] 1

#### Syntax

```

assignment_statement ::=
 variable_name := expression;

```

The execution of an `assignment_statement` includes the evaluation of the `expression` and the *assignment* of the value of the `expression` into the *target*. [An assignment operation (as opposed to an `assignment_statement`) is performed in other contexts as well, including object initialization and by-

copy parameter passing.] The *target* of an assignment operation is the view of the object to which a value is being assigned; the target of an `assignment_statement` is the variable denoted by the *variable\_name*.

- 3.a **Discussion:** Don't confuse this notion of the “target” of an assignment with the notion of the “target object” of an entry call or `queue`.
- 3.b Don't confuse the term “assignment operation” with the `assignment_statement`. The assignment operation is just one part of the execution of an `assignment_statement`. The assignment operation is also a part of the execution of various other constructs; see 7.6.1, “Completion and Finalization” for a complete list. Note that when we say, “such-and-such is assigned to so-and-so”, we mean that the assignment operation is being applied, and that so-and-so is the target of the assignment operation.

#### *Name Resolution Rules*

4/2 {AI95-00287-01} The *variable\_name* of an `assignment_statement` is expected to be of any type. The expected type for the expression is the type of the target.

4.a **Implementation Note:** An `assignment_statement` as a whole is a “complete context,” so if the *variable\_name* of an `assignment_statement` is overloaded, the expression can be used to help disambiguate it. For example:

```
4.b type P1 is access R1;
 type P2 is access R2;
4.c function F return P1;
 function F return P2;
4.d X : R1;
 begin
 F.all := X; -- Right hand side helps resolve left hand side
```

#### *Legality Rules*

5/2 {AI95-00287-01} The target [denoted by the *variable\_name*] shall be a variable of a nonlimited type.

6 If the target is of a tagged class-wide type *T*Class, then the expression shall either be dynamically tagged, or of type *T* and tag-indeterminate (see 3.9.2).

6.a **Reason:** This is consistent with the general rule that a single dispatching operation shall not have both dynamically tagged and statically tagged operands. Note that for an object initialization (as opposed to the `assignment_statement`), a statically tagged initialization expression is permitted, since there is no chance for confusion (or `Tag_Check` failure). Also, in an object initialization, tag-indeterminate expressions of any type covered by *T*Class would be allowed, but with an `assignment_statement`, that might not work if the tag of the target was for a type that didn't have one of the dispatching operations in the tag-indeterminate expression.

#### *Dynamic Semantics*

7 For the execution of an `assignment_statement`, the *variable\_name* and the expression are first evaluated in an arbitrary order.

7.a **Ramification:** Other rules of the language may require that the bounds of the variable be determined prior to evaluating the expression, but that does not necessarily require evaluation of the *variable\_name*, as pointed out by the ACID.

8 When the type of the target is class-wide:

- 9 • If the expression is tag-indeterminate (see 3.9.2), then the controlling tag value for the expression is the tag of the target;

9.a **Ramification:** See 3.9.2, “Dispatching Operations of Tagged Types”.

- 10 • Otherwise [(the expression is dynamically tagged)], a check is made that the tag of the value of the expression is the same as that of the target; if this check fails, `Constraint_Error` is raised.

11 The value of the expression is converted to the subtype of the target. [The conversion might raise an exception (see 4.6).]

11.a **Ramification:** 4.6, “Type Conversions” defines what actions and checks are associated with subtype conversion. For non-array subtypes, it is just a constraint check presuming the types match. For array subtypes, it checks the lengths and slides if the target is constrained. “Sliding” means the array doesn't have to have the same bounds, so long as it is the same length.

In cases involving controlled types, the target is finalized, and an anonymous object might be used as an intermediate in the assignment, as described in 7.6.1, “Completion and Finalization”. In any case, the converted value of the expression is then *assigned* to the target, which consists of the following two steps:

- **To be honest:** 7.6.1 actually says that finalization happens always, but unless controlled types are involved, this finalization during an `assignment_statement` does nothing. 12.a
  - The value of the target becomes the converted value. 13
  - *{AI05-0299-1}* If any part of the target is controlled, its value is adjusted as explained in subclause 7.6. 14/3
- Ramification:** If any parts of the object are controlled, abort is deferred during the assignment operation itself, but not during the rest of the execution of an `assignment_statement`. 14.a

## NOTES

2 The tag of an object never changes; in particular, an `assignment_statement` does not change the tag of the target. 15

*This paragraph was deleted. {AI95-00363-01}* 16/2

**Ramification:** The implicit subtype conversion described above for `assignment_statements` is performed only for the value of the right-hand side expression as a whole; it is not performed for subcomponents of the value. 16.a

The determination of the type of the variable of an `assignment_statement` may require consideration of the expression if the variable name can be interpreted as the name of a variable designated by the access value returned by a function call, and similarly, as a component or slice of such a variable (see 8.6, “The Context of Overload Resolution”). 16.b

*Examples*

*Examples of assignment statements:* 17

```
Value := Max_Value - 1; 18
Shade := Blue;
```

```
Next_Frame(F) (M, N) := 2.5; -- see 4.1.1 19
U := Dot_Product(V, W); -- see 6.3
```

```
Writer := (Status => Open, Unit => Printer, Line_Count => 60); -- see 3.8.1 20
Next_Car.all := (72074, null); -- see 3.10.1
```

*Examples involving scalar subtype conversions:* 21

```
I, J : Integer range 1 .. 10 := 5; 22
K : Integer range 1 .. 20 := 15;
...
```

```
I := J; -- identical ranges 23
K := J; -- compatible ranges
J := K; -- will raise Constraint_Error if K > 10
```

*Examples involving array subtype conversions:* 24

```
A : String(1 .. 31); 25
B : String(3 .. 33);
...
```

```
A := B; -- same number of components 26
```

```
A(1 .. 9) := "tar sauce"; 27
A(4 .. 12) := A(1 .. 9); -- A(1 .. 12) = "tartar sauce"
```

## NOTES

3 *Notes on the examples:* `Assignment_statements` are allowed even in the case of overlapping slices of the same array, because the `variable_name` and `expression` are both evaluated before copying the value into the variable. In the above example, an implementation yielding `A(1 .. 12) = "tartartartar"` would be incorrect. 28

*Extensions to Ada 83*

We now allow user-defined finalization and value adjustment actions as part of `assignment_statements` (see 7.6, “Assignment and Finalization”). 28.a

*Wording Changes from Ada 83*

- 28.b The special case of array assignment is subsumed by the concept of a subtype conversion, which is applied for all kinds of types, not just arrays. For arrays it provides “sliding”. For numeric types it provides conversion of a value of a universal type to the specific type of the target. For other types, it generally has no run-time effect, other than a constraint check.
- 28.c We now cover in a general way in 3.7.2 the erroneous execution possible due to changing the value of a discriminant when the variable in an `assignment_statement` is a subcomponent that depends on discriminants.

*Incompatibilities With Ada 95*

- 28.d/2 {AI95-00287-01} The change of the limited check from a resolution rule to a legality rule is not quite upward compatible. For example
- 28.e/2
- ```

type AccNonLim is access NonLim;
function Foo (Arg : in Integer) return AccNonLim;
type AccLim is access Lim;
function Foo (Arg : in Integer) return AccLim;
Foo(2).all := Foo(1).all;

```
- 28.f/2 where NonLim is a nonlimited type and Lim is a limited type. The assignment is legal in Ada 95 (only the first Foo would be considered), and is ambiguous in Ada 2005. We made the change because we want limited types to be as similar to nonlimited types as possible. Limited expressions are now allowed in all other contexts (with a similar incompatibility), and it would be odd if assignments had different resolution rules (which would eliminate ambiguities in some cases). Moreover, examples like this one are rare, as they depend on assigning into overloaded function calls.

5.3 If Statements

- 1 [An `if_statement` selects for execution at most one of the enclosed `sequences_of_statements`, depending on the (truth) value of one or more corresponding conditions.]

Syntax

- 2
- ```

if_statement ::=
 if condition then
 sequence_of_statements
 {elsif condition then
 sequence_of_statements}
 [else
 sequence_of_statements]
 end if;

```

Paragraphs 3 and 4 were deleted.

*Dynamic Semantics*

- 5/3 {AI05-0264-1} For the execution of an `if_statement`, the condition specified after `if`, and any conditions specified after `elsif`, are evaluated in succession (treating a final `else` as `elsif True then`), until one evaluates to True or all conditions are evaluated and yield False. If a condition evaluates to True, then the corresponding `sequence_of_statements` is executed; otherwise, none of them is executed.
- 5.a **Ramification:** The part about all evaluating to False can't happen if there is an `else`, since that is herein considered equivalent to `elsif True then`.

*Examples*

- 6 *Examples of if statements:*
- 7
- ```

if Month = December and Day = 31 then
  Month := January;
  Day   := 1;
  Year  := Year + 1;
end if;

```

```

if Line_Too_Short then
    raise Layout_Error;
elsif Line_Full then
    New_Line;
    Put (Item);
else
    Put (Item);
end if;

if My_Car.Owner.Vehicle /= My_Car then
    Report ("Incorrect data");
end if;

```

8

9

-- see 3.10.1

Wording Changes from Ada 2005

{AI05-0147-1} Moved definition of condition to 4.5.7 in order to eliminate a forward reference. 9.a/3

5.4 Case Statements

[A `case_statement` selects for execution one of a number of alternative `sequences_of_statements`; the chosen alternative is defined by the value of an expression.] 1

Syntax

```

{AI05-0188-1} case_statement ::=
    case selecting_expression is
        case_statement_alternative
        {case_statement_alternative}
    end case;

case_statement_alternative ::=
    when discrete_choice_list =>
        sequence_of_statements

```

2/3

3

Name Resolution Rules

{AI05-0188-1} The `selecting_expression` is expected to be of any discrete type. The expected type for each `discrete_choice` is the type of the `selecting_expression`. 4/3

Legality Rules

{AI05-0153-3} The `choice_expressions`, `subtype_indications`, and `ranges` given as `discrete_choices` of a `case_statement` shall be static. [A `discrete_choice others`, if present, shall appear alone and in the last `discrete_choice_list`.] 5/3

{AI05-0188-1} {AI05-0240-1} The possible values of the `selecting_expression` shall be covered (see 3.8.1) as follows: 6/3

Discussion: {AI05-0240-1} The meaning of "covered" here and in the following rules is that of the term "cover a value" that is defined in 3.8.1. 6.a/3

- {AI05-0003-1} {AI05-0153-3} {AI05-0188-1} {AI05-0262-1} If the `selecting_expression` is a name [(including a `type_conversion`, `qualified_expression`, or `function_call`)] having a static and constrained nominal subtype, then each non-**others** `discrete_choice` shall cover only values in that subtype that satisfy its predicate (see 3.2.4), and each value of that subtype that satisfies its predicate shall be covered by some `discrete_choice` [(either explicitly or by **others**)]. 7/3

Ramification: Although not official names of objects, a value conversion still has a defined nominal subtype, namely its target subtype. See 4.6. 7.a

- {AI05-0188-1} If the type of the `selecting_expression` is `root_integer`, `universal_integer`, or a descendant of a formal scalar type, then the `case_statement` shall have an **others** `discrete_choice`. 8/3

- 8.a **Reason:** This is because the base range is implementation defined for *root_integer* and *universal_integer*, and not known statically in the case of a formal scalar type.
- 9/3 • *{AI05-0188-1}* Otherwise, each value of the base range of the type of the *selecting_expression* shall be covered [(either explicitly or by **others**)].
- 10 Two distinct *discrete_choices* of a *case_statement* shall not cover the same value.
- 10.a/3 **Ramification:** *{AI05-0188-1}* The goal of these coverage rules is that any possible value of the *selecting_expression* of a *case_statement* should be covered by exactly one *discrete_choice* of the *case_statement*, and that this should be checked at compile time. The goal is achieved in most cases, but there are two minor loopholes:
- 10.b • If the expression reads an object with an invalid representation (e.g. an uninitialized object), then the value can be outside the covered range. This can happen for static constrained subtypes, as well as nonstatic or unconstrained subtypes. It cannot, however, happen if the *case_statement* has the *discrete_choice others*, because **others** covers all values, even those outside the subtype.
- 10.c/3 • *{AI95-00114-01}* *{AI05-0188-1}* If the compiler chooses to represent the value of an expression of an unconstrained subtype in a way that includes values outside the bounds of the subtype, then those values can be outside the covered range. For example, if *X: Integer := Integer'Last;*, and the *case selecting_expression* is *X+1*, then the implementation might choose to produce the correct value, which is outside the bounds of *Integer*. (It might raise *Constraint_Error* instead.) This case can only happen for nongeneric subtypes that are either unconstrained or nonstatic (or both). It can only happen if there is no **others** *discrete_choice*.
- 10.d In the uninitialized variable case, the value might be anything; hence, any alternative can be chosen, or *Constraint_Error* can be raised. (We intend to prevent, however, jumping to random memory locations and the like.) In the out-of-range case, the behavior is more sensible: if there is an **others**, then the implementation may choose to raise *Constraint_Error* on the evaluation of the *expression* (as usual), or it may choose to correctly evaluate the *expression* and therefore choose the **others** alternative. Otherwise (no **others**), *Constraint_Error* is raised either way — on the *expression* evaluation, or for the *case_statement* itself.
- 10.e For an enumeration type with a discontinuous set of internal codes (see 13.4), the only way to get values in between the proper values is via an object with an invalid representation; there is no “out-of-range” situation that can produce them.

Dynamic Semantics

- 11/3 *{AI05-0188-1}* For the execution of a *case_statement* the *selecting_expression* is first evaluated.
- 12/3 *{AI05-0188-1}* If the value of the *selecting_expression* is covered by the *discrete_choice_list* of some *case_statement_alternative*, then the *sequence_of_statements* of the *_alternative* is executed.
- 13 Otherwise (the value is not covered by any *discrete_choice_list*, perhaps due to being outside the base range), *Constraint_Error* is raised.
- 13.a **Ramification:** In this case, the value is outside the base range of its type, or is an invalid representation.

NOTES

- 14 4 The execution of a *case_statement* chooses one and only one alternative. Qualification of the *expression* of a *case_statement* by a static subtype can often be used to limit the number of choices that need be given explicitly.

*Examples*15 *Examples of case statements:*

```

16  case Sensor is
    when Elevation => Record_Elevation(Sensor_Value);
    when Azimuth   => Record_Azimuth  (Sensor_Value);
    when Distance  => Record_Distance (Sensor_Value);
    when others    => null;
  end case;

17  case Today is
    when Mon       => Compute_Initial_Balance;
    when Fri       => Compute_Closing_Balance;
    when Tue .. Thu => Generate_Report(Today);
    when Sat .. Sun => null;
  end case;

```

```

case Bin_Number(Count) is
  when 1    => Update_Bin(1);
  when 2    => Update_Bin(2);
  when 3 | 4 =>
    Empty_Bin(1);
    Empty_Bin(2);
  when others => raise Error;
end case;

```

18

Incompatibilities With Ada 83

In Ada 95, `function_calls` and `type_conversions` are names, whereas in Ada 83, they were expressions. Therefore, if the expression of a `case_statement` is a `function_call` or `type_conversion`, and the result subtype is static, it is illegal to specify a choice outside the bounds of the subtype. For this case in Ada 83 choices only are required to be in the base range of the type. 18.a.1/1

In addition, the rule about which choices must be covered is unchanged in Ada 95. Therefore, for a `case_statement` whose expression is a `function_call` or `type_conversion`, Ada 83 required covering all choices in the base range, while Ada 95 only requires covering choices in the bounds of the subtype. If the `case_statement` does not include an `others` `discrete_choice`, then a legal Ada 83 `case_statement` will be illegal in Ada 95 if the bounds of the subtype are different than the bounds of the base type. 18.a.2/1

Extensions to Ada 83

In Ada 83, the expression in a `case_statement` is not allowed to be of a generic formal type. This restriction is removed in Ada 95; an `others` `discrete_choice` is required instead. 18.a

In Ada 95, a function call is the name of an object; this was not true in Ada 83 (see 4.1, “Names”). This change makes the following `case_statement` legal: 18.b

```

subtype S is Integer range 1..2;
function F return S;
case F is
  when 1 => ...;
  when 2 => ...;
  -- No others needed.
end case;

```

18.c

{AI05-0005-1} Note that the result subtype given in a function renaming declaration is ignored; for a `case_statement` whose expression calls a such a function, the full coverage rules are checked using the result subtype of the original function. Note that predefined operators such as “+” have an unconstrained result subtype (see 4.5.1). Note that generic formal functions do not have static result subtypes. Note that the result subtype of an inherited subprogram need not correspond to any nameable subtype; there is still a perfectly good result subtype, though. 18.d/3

Wording Changes from Ada 83

Ada 83 forgot to say what happens for “legally” out-of-bounds values. 18.e

We take advantage of rules and terms (e.g. *cover a value*) defined for `discrete_choices` and `discrete_choice_lists` in 3.8.1, “Variant Parts and Discrete Choices”. 18.f

In the Name Resolution Rule for the case expression, we no longer need RM83-5.4(3)’s “which must be determinable independently of the context in which the expression occurs, but using the fact that the expression must be of a discrete type,” because the expression is now a complete context. See 8.6, “The Context of Overload Resolution”. 18.g

Since `type_conversions` are now defined as names, their coverage rule is now covered under the general rule for names, rather than being separated out along with `qualified_expressions`. 18.h

Wording Changes from Ada 2005

{AI05-0003-1} Rewording to reflect that a `qualified_expression` is now a name. 18.i/3

{AI05-0153-3} Revised for changes to `discrete_choices` made to allow static predicates (see 3.2.4) as case choices (see 3.8.1). 18.j/3

{AI05-0188-1} Added the *selecting_* prefix to make this wording consistent with `case_expression`, and to clarify which expression is being talked about in the wording. 18.k/3

5.5 Loop Statements

1 [A `loop_statement` includes a `sequence_of_statements` that is to be executed repeatedly, zero or more times.]

Syntax

2 `loop_statement ::=`
 `[loop_statement_identifier:]`
 `[iteration_scheme] loop`
 `sequence_of_statements`
 `end loop [loop_identifier];`

3/3 `{AI05-0139-2}` `iteration_scheme ::= while condition`
 `| for loop_parameter_specification`
 `| for iterator_specification`

4 `loop_parameter_specification ::=`
 `defining_identifier in [reverse] discrete_subtype_definition`

5 If a `loop_statement` has a `loop_statement_identifier`, then the identifier shall be repeated after the `end loop`; otherwise, there shall not be an identifier after the `end loop`.

Static Semantics

6 A `loop_parameter_specification` declares a *loop parameter*, which is an object whose subtype is that defined by the `discrete_subtype_definition`.

Dynamic Semantics

7 For the execution of a `loop_statement`, the `sequence_of_statements` is executed repeatedly, zero or more times, until the `loop_statement` is complete. The `loop_statement` is complete when a transfer of control occurs that transfers control out of the loop, or, in the case of an `iteration_scheme`, as specified below.

8 For the execution of a `loop_statement` with a **while** `iteration_scheme`, the condition is evaluated before each execution of the `sequence_of_statements`; if the value of the condition is True, the `sequence_of_statements` is executed; if False, the execution of the `loop_statement` is complete.

9/3 `{AI05-0139-2}` `{AI05-0262-1}` For the execution of a `loop_statement` with the `iteration_scheme` being **for** `loop_parameter_specification`, the `loop_parameter_specification` is first elaborated. This elaboration creates the loop parameter and elaborates the `discrete_subtype_definition`. If the `discrete_subtype_definition` defines a subtype with a null range, the execution of the `loop_statement` is complete. Otherwise, the `sequence_of_statements` is executed once for each value of the discrete subtype defined by the `discrete_subtype_definition` that satisfies the predicate of the subtype (or until the loop is left as a consequence of a transfer of control). Prior to each such iteration, the corresponding value of the discrete subtype is assigned to the loop parameter. These values are assigned in increasing order unless the reserved word **reverse** is present, in which case the values are assigned in decreasing order.

9.a **Ramification:** The order of creating the loop parameter and evaluating the `discrete_subtype_definition` doesn't matter, since the creation of the loop parameter has no side effects (other than possibly raising `Storage_Error`, but anything can do that).

9.b/3 `{AI05-0262-1}` The predicate (if any) necessarily has to be a static predicate as a dynamic predicate is explicitly disallowed — see 3.2.4.

9.c/3 **Reason:** `{AI05-0262-1}` If there is a predicate, the loop still visits the values in the order of the underlying base type; the order of the values in the predicate is irrelevant. This is the case so that the following loops have the same sequence of calls and parameters on procedure `Call` for any subtype `S`:

```

for I in S loop
    Call (I);
end loop;
for I in S'Base loop
    if I in S then
        Call (I);
    end if;
end loop;

```

{AI05-0262-1} [For details about the execution of a loop_statement with the iteration_scheme being for iterator_specification, see 5.5.2.] 9.1/3

NOTES

5 A loop parameter is a constant; it cannot be updated within the sequence_of_statements of the loop (see 3.3). 10

6 An object_declaration should not be given for a loop parameter, since the loop parameter is automatically declared by the loop_parameter_specification. The scope of a loop parameter extends from the loop_parameter_specification to the end of the loop_statement, and the visibility rules are such that a loop parameter is only visible within the sequence_of_statements of the loop. 11

Implementation Note: An implementation could give a warning if a variable is hidden by a loop_parameter_specification. 11.a

7 The discrete_subtype_definition of a for loop is elaborated just once. Use of the reserved word **reverse** does not alter the discrete subtype defined, so that the following iteration_schemes are not equivalent; the first has a null range. 12

```

for J in reverse 1 .. 0
for J in 0 .. 1

```

Ramification: If a loop_parameter_specification has a static discrete range, the subtype of the loop parameter is static. 13.a

Examples

Example of a loop statement without an iteration scheme: 14

```

loop
    Get (Current_Character);
    exit when Current_Character = '*';
end loop;

```

Example of a loop statement with a while iteration scheme: 16

```

while Bid(N).Price < Cut_Off.Price loop
    Record_Bid(Bid(N).Price);
    N := N + 1;
end loop;

```

Example of a loop statement with a for iteration scheme: 18

```

for J in Buffer'Range loop -- works even with a null range
    if Buffer(J) /= Space then
        Put (Buffer(J));
    end if;
end loop;

```

Example of a loop statement with a name: 20

```

Summation:
while Next /= Head loop -- see 3.10.1
    Sum := Sum + Next.Value;
    Next := Next.Succ;
end loop Summation;

```

Wording Changes from Ada 83

The constant-ness of loop parameters is specified in 3.3, “Objects and Named Numbers”. 21.a

- 21.b/3 {AI05-0139-2} {AI05-0262-1} {AI05-0299-1} Generalized iterator_specifications are allowed in **for** loops; these are documented as an extension in the appropriate subclause.

5.5.1 User-Defined Iterator Types

Static Semantics

- 1/3 {AI05-0139-2} The following language-defined generic library package exists:

```

2/3   generic
      type Cursor;
      with function Has_Element (Position : Cursor) return Boolean;
   package Ada.Iterator_Interfaces is
      pragma Pure (Iterator_Interfaces);
3/3   type Forward_Iterator is limited interface;
      function First (Object : Forward_Iterator) return Cursor is abstract;
      function Next (Object : Forward_Iterator; Position : Cursor)
          return Cursor is abstract;
4/3   type Reversible_Iterator is limited interface and Forward_Iterator;
      function Last (Object : Reversible_Iterator) return Cursor is abstract;
      function Previous (Object : Reversible_Iterator; Position : Cursor)
          return Cursor is abstract;
5/3   end Ada.Iterator_Interfaces;
```

- 6/3 {AI05-0139-2} An *iterator type* is a type descended from the `Forward_Iterator` interface from some instance of `Ada.Iterator_Interfaces`. A *reversible iterator type* is a type descended from the `Reversible_Iterator` interface from some instance of `Ada.Iterator_Interfaces`. An *iterator object* is an object of an iterator type. A *reversible iterator object* is an object of a reversible iterator type. The formal subtype `Cursor` from the associated instance of `Ada.Iterator_Interfaces` is the *iteration cursor subtype* for the iterator type.

- 7/3 {AI05-0139-2} {AI05-0292-1} The following type-related operational aspects may be specified for an indexable container type *T* (see 4.1.6):

8/3 Default_Iterator

This aspect is specified by a **name** that denotes exactly one function declared immediately within the same declaration list in which *T* is declared, whose first parameter is of type *T* or *TClass* or an access parameter whose designated type is type *T* or *TClass*, whose other parameters, if any, have default expressions, and whose result type is an iterator type. This function is the *default iterator function* for *T*. Its result subtype is the *default iterator subtype* for *T*. The iteration cursor subtype for the default iterator subtype is the *default cursor subtype* for *T*.

- 8.a/3 **Aspect Description for Default_Iterator:** Default iterator to be used in **for** loops.

9/3 Iterator_Element

This aspect is specified by a **name** that denotes a subtype. This is the *default element subtype* for *T*.

- 9.a/3 **Aspect Description for Iterator_Element:** Element type to be used for user-defined iterators.

10/3 These aspects are inherited by descendants of type *T* (including *TClass*).

- 11/3 {AI05-0139-2} {AI05-0292-1} An *iterable container type* is an indexable container type with specified `Default_Iterator` and `Iterator_Element` aspects. A *reversible iterable container type* is an iterable container type with the default iterator type being a reversible iterator type. An *iterable container object* is an object of an iterable container type. A *reversible iterable container object* is an object of a reversible iterable container type.

Glossary entry: An iterable container type is one that has user-defined behavior for iteration, via the `Default_Iterator` and `Iterator_Element` aspects. 11.a.1/3

Legality Rules

{AI05-0139-2} {AI05-0292-1} The `Constant_Indexing` aspect (if any) of an iterable container type *T* shall denote exactly one function with the following properties: 12/3

- the result type of the function is covered by the default element type of *T* or is a reference type (see 4.1.5) with an access discriminant designating a type covered by the default element type of *T*; 13/3
- the type of the second parameter of the function covers the default cursor type for *T*; 14/3
- if there are more than two parameters, the additional parameters all have default expressions. 15/3

This function (if any) is the *default constant indexing function* for *T*. 16/3

Ramification: This does not mean that `Constant_Indexing` has to designate only one subprogram, only that there is only one routine that meets all of these properties. There can be other routines designated by `Constant_Indexing`, but they cannot have the profile described above. For instance, map containers have a version of `Constant_Indexing` that takes a key instead of a cursor; this is allowed. 16.a/3

{AI05-0139-2} {AI05-0292-1} The `Variable_Indexing` aspect (if any) of an iterable container type *T* shall denote exactly one function with the following properties: 17/3

- the result type of the function is a reference type (see 4.1.5) with an access discriminant designating a type covered by the default element type of *T*; 18/3
- the type of the second parameter of the function covers the default cursor type for *T*; 19/3
- if there are more than two parameters, the additional parameters all have default expressions. 20/3

This function (if any) is the *default variable indexing function* for *T*. 21/3

Extensions to Ada 2005

{AI05-0139-2} User-defined iterator types are new in Ada 2012. 21.a/3

5.5.2 Generalized Loop Iteration

{AI05-0139-2} Generalized forms of loop iteration are provided by an `iterator_specification`. 1/3

Syntax

{AI05-0139-2} {AI05-0292-1} `iterator_specification ::=`
`defining_identifier in [reverse] iterator_name`
`| defining_identifier [: subtype_indication] of [reverse] iterable_name` 2/3

Name Resolution Rules

{AI05-0139-2} {AI05-0292-1} For the first form of `iterator_specification`, called a *generalized iterator*, the expected type for the `iterator_name` is any iterator type. For the second form of `iterator_specification`, the expected type for the `iterable_name` is any array or iterable container type. If the `iterable_name` denotes an array object, the `iterator_specification` is called an *array component iterator*; otherwise it is called a *container element iterator*. 3/3

Glossary entry: An iterator is a construct that is used to loop over the elements of an array or container. Iterators may be user defined, and may perform arbitrary computations to access elements from a container. 3.a.1/3

Legality Rules

{AI05-0139-2} If the reserved word **reverse** appears, the `iterator_specification` is a *reverse iterator*; otherwise it is a *forward iterator*. In a reverse generalized iterator, the `iterator_name` shall be of a 4/3

reversible iterator type. In a reverse container element iterator, the default iterator type for the type of the *iterable_name* shall be a reversible iterator type.

- 5/3 {AI05-0139-2} The type of the *subtype_indication*, if any, of an array component iterator shall cover the component type of the type of the *iterable_name*. The type of the *subtype_indication*, if any, of a container element iterator shall cover the default element type for the type of the *iterable_name*.
- 6/3 {AI05-0139-2} In a container element iterator whose *iterable_name* has type *T*, if the *iterable_name* denotes a constant or the *Variable_Indexing* aspect is not specified for *T*, then the *Constant_Indexing* aspect shall be specified for *T*.

Static Semantics

- 7/3 {AI05-0139-2} {AI05-0269-1} {AI05-0292-1} An *iterator_specification* declares a *loop_parameter*. In a generalized iterator, the nominal subtype of the loop parameter is the iteration cursor subtype. In an array component iterator or a container element iterator, if a *subtype_indication* is present, it determines the nominal subtype of the loop parameter. In an array component iterator, if a *subtype_indication* is not present, the nominal subtype of the loop parameter is the component subtype of the type of the *iterable_name*. In a container element iterator, if a *subtype_indication* is not present, the nominal subtype of the loop parameter is the default element subtype for the type of the *iterable_name*.
- 8/3 {AI05-0139-2} {AI05-0292-1} In a generalized iterator, the loop parameter is a constant. In an array component iterator, the loop parameter is a constant if the *iterable_name* denotes a constant; otherwise it denotes a variable. In a container element iterator, the loop parameter is a constant if the *iterable_name* denotes a constant, or if the *Variable_Indexing* aspect is not specified for the type of the *iterable_name*; otherwise it is a variable.

Dynamic Semantics

- 9/3 {AI05-0139-2} For the execution of a *loop_statement* with an *iterator_specification*, the *iterator_specification* is first elaborated. This elaboration elaborates the *subtype_indication*, if any.
- 10/3 {AI05-0139-2} For a generalized iterator, the loop parameter is created, the *iterator_name* is evaluated, and the denoted iterator object becomes the *loop_iterator*. In a forward generalized iterator, the operation *First* of the iterator type is called on the loop iterator, to produce the initial value for the loop parameter. If the result of calling *Has_Element* on the initial value is *False*, then the execution of the *loop_statement* is complete. Otherwise, the *sequence_of_statements* is executed and then the *Next* operation of the iterator type is called with the loop iterator and the current value of the loop parameter to produce the next value to be assigned to the loop parameter. This repeats until the result of calling *Has_Element* on the loop parameter is *False*, or the loop is left as a consequence of a transfer of control. For a reverse generalized iterator, the operations *Last* and *Previous* are called rather than *First* and *Next*.
- 11/3 {AI05-0139-2} {AI05-0292-1} For an array component iterator, the *iterable_name* is evaluated and the denoted array object becomes the *array for the loop*. If the array for the loop is a null array, then the execution of the *loop_statement* is complete. Otherwise, the *sequence_of_statements* is executed with the loop parameter denoting each component of the array for the loop, using a *canonical* order of components, which is last dimension varying fastest (unless the array has convention *Fortran*, in which case it is first dimension varying fastest). For a forward array component iterator, the iteration starts with the component whose index values are each the first in their index range, and continues in the canonical order. For a reverse array component iterator, the iteration starts with the component whose index values are each the last in their index range, and continues in the reverse of the canonical order. The loop iteration proceeds until the *sequence_of_statements* has been executed for each component of the array for the loop, or until the loop is left as a consequence of a transfer of control.

{AI05-0139-2} {AI05-0292-1} For a container element iterator, the *iterable_name* is evaluated and the denoted iterable container object becomes the *iterable container object for the loop*. The default iterator function for the type of the iterable container object for the loop is called on the iterable container object and the result is the *loop iterator*. An object of the default cursor subtype is created (the *loop cursor*). 12/3

{AI05-0139-2} {AI05-0292-1} For a forward container element iterator, the operation First of the iterator type is called on the loop iterator, to produce the initial value for the loop cursor. If the result of calling Has_Element on the initial value is False, then the execution of the *loop_statement* is complete. Otherwise, the *sequence_of_statements* is executed with the loop parameter denoting an indexing (see 4.1.6) into the iterable container object for the loop, with the only parameter to the indexing being the current value of the loop cursor; then the Next operation of the iterator type is called with the loop iterator and the loop cursor to produce the next value to be assigned to the loop cursor. This repeats until the result of calling Has_Element on the loop cursor is False, or until the loop is left as a consequence of a transfer of control. For a reverse container element iterator, the operations Last and Previous are called rather than First and Next. If the loop parameter is a constant (see above), then the indexing uses the default constant indexing function for the type of the iterable container object for the loop; otherwise it uses the default variable indexing function. 13/3

Examples

```
{AI05-0269-1} -- Array component iterator example:
for Element of Board loop -- See 3.6.1.
  Element := Element * 2.0; -- Double each element of Board, a two-dimensional array.
end loop;
```

14/3

{AI05-0268-1} For examples of use of generalized iterators, see A.18.32 and the corresponding container packages in A.18.2 and A.18.3. 15/3

Extensions to Ada 2005

{AI05-0139-2} Generalized forms of loop iteration are new. 15.a/3

5.6 Block Statements

[A *block_statement* encloses a *handled_sequence_of_statements* optionally preceded by a *declarative_part*.] 1

Syntax

```
block_statement ::=
  [block_statement_identifier:]
  [declare
    declarative_part]
  begin
    handled_sequence_of_statements
  end [block_identifier];
```

2

If a *block_statement* has a *block_statement_identifier*, then the identifier shall be repeated after the **end**; otherwise, there shall not be an identifier after the **end**. 3

Static Semantics

A *block_statement* that has no explicit *declarative_part* has an implicit empty *declarative_part*. 4

Ramification: Thus, other rules can always refer to the *declarative_part* of a *block_statement*. 4.a

Dynamic Semantics

- 5 The execution of a `block_statement` consists of the elaboration of its `declarative_part` followed by the execution of its `handled_sequence_of_statements`.

Examples

- 6 *Example of a block statement with a local variable:*

```
7 Swap:
  declare
    Temp : Integer;
  begin
    Temp := V; V := U; U := Temp;
  end Swap;
```

- 7.a **Ramification:** If task objects are declared within a `block_statement` whose execution is completed, the `block_statement` is not left until all its dependent tasks are terminated (see 7.6). This rule applies to completion caused by a transfer of control.
- 7.b Within a `block_statement`, the block name can be used in expanded names denoting local entities such as `Swap.Temp` in the above example (see 4.1.3).

Wording Changes from Ada 83

- 7.c The syntax rule for `block_statement` now uses the syntactic category `handled_sequence_of_statements`.

5.7 Exit Statements

- 1 [An `exit_statement` is used to complete the execution of an enclosing `loop_statement`; the completion is conditional if the `exit_statement` includes a `condition`.]

Syntax

```
2 exit_statement ::=
  exit [loop_name] [when condition];
```

Name Resolution Rules

- 3 The `loop_name`, if any, in an `exit_statement` shall resolve to denote a `loop_statement`.

Legality Rules

- 4 Each `exit_statement` *applies to* a `loop_statement`; this is the `loop_statement` being exited. An `exit_statement` with a name is only allowed within the `loop_statement` denoted by the name, and applies to that `loop_statement`. An `exit_statement` without a name is only allowed within a `loop_statement`, and applies to the innermost enclosing one. An `exit_statement` that applies to a given `loop_statement` shall not appear within a body or `accept_statement`, if this construct is itself enclosed by the given `loop_statement`.

Dynamic Semantics

- 5 For the execution of an `exit_statement`, the `condition`, if present, is first evaluated. If the value of the `condition` is `True`, or if there is no `condition`, a transfer of control is done to complete the `loop_statement`. If the value of the `condition` is `False`, no transfer of control takes place.

NOTES

- 6 8 Several nested loops can be exited by an `exit_statement` that names the outer loop.

Examples

- 7 *Examples of loops with exit statements:*

```

for N in 1 .. Max_Num_Items loop
  Get_New_Item(New_Item);
  Merge_Item(New_Item, Storage_File);
  exit when New_Item = Terminal_Item;
end loop;
Main_Cycle:
loop
  -- initial statements
  exit Main_Cycle when Found;
  -- final statements
end loop Main_Cycle;

```

5.8 Goto Statements

[A `goto_statement` specifies an explicit transfer of control from this statement to a target statement with a given label.]

Syntax

```
goto_statement ::= goto label_name;
```

Name Resolution Rules

The *label_name* shall resolve to denote a label; the statement with that label is the *target statement*.

Legality Rules

The innermost `sequence_of_statements` that encloses the target statement shall also enclose the `goto_statement`. Furthermore, if a `goto_statement` is enclosed by an `accept_statement` or a body, then the target statement shall not be outside this enclosing construct.

Ramification: The `goto_statement` can be a statement of an inner `sequence_`. 4.a

It follows from the second rule that if the target statement is enclosed by such a construct, then the `goto_statement` cannot be outside. 4.b

Dynamic Semantics

The execution of a `goto_statement` transfers control to the target statement, completing the execution of any `compound_statement` that encloses the `goto_statement` but does not enclose the target. 5

NOTES

9 The above rules allow transfer of control to a statement of an enclosing `sequence_of_statements` but not the reverse. Similarly, they prohibit transfers of control such as between alternatives of a `case_statement`, `if_statement`, or `select_statement`; between `exception_handlers`; or from an `exception_handler` of a `handled_sequence_of_statements` back to its `sequence_of_statements`. 6

Examples

Example of a loop containing a goto statement: 7

```

<<Sort>>
for I in 1 .. N-1 loop
  if A(I) > A(I+1) then
    Exchange(A(I), A(I+1));
    goto Sort;
  end if;
end loop;

```

6 Subprograms

A subprogram is a program unit or intrinsic operation whose execution is invoked by a subprogram call. There are two forms of subprogram: procedures and functions. A procedure call is a **statement**; a function call is an expression and returns a value. The definition of a subprogram can be given in two parts: a subprogram declaration defining its interface, and a `subprogram_body` defining its execution. [Operators and enumeration literals are functions.] 1

To be honest: A function call is an expression, but more specifically it is a name. 1.a

Glossary entry: A subprogram is a section of a program that can be executed in various contexts. It is invoked by a subprogram call that may qualify the effect of the subprogram through the passing of parameters. There are two forms of subprograms: functions, which return values, and procedures, which do not. 1.b/2

Glossary entry: A function is a form of subprogram that returns a result and can be called as part of an expression. 1.c/2

Glossary entry: A procedure is a form of subprogram that does not return a result and can only be called by a statement. 1.d/2

{AI05-0299-1} A *callable entity* is a subprogram or entry (see Section 9). A callable entity is invoked by a *call*; that is, a subprogram call or entry call. A *callable construct* is a construct that defines the action of a call upon a callable entity: a `subprogram_body`, `entry_body`, or `accept_statement`. 2/3

Ramification: Note that “callable entity” includes predefined operators, enumeration literals, and abstract subprograms. “Call” includes calls of these things. They do not have callable constructs, since they don't have completions. 2.a

6.1 Subprogram Declarations

[A `subprogram_declaration` declares a procedure or function.] 1

Syntax

{AI95-00218-03} {AI05-0183-1} `subprogram_declaration` ::= 2/3
 [overriding_indicator]
 subprogram_specification
 [aspect_specification];

This paragraph was deleted. {AI95-00348-01} 3/2

{AI95-00348-01} `subprogram_specification` ::= 4/2
 procedure_specification
 | function_specification

{AI95-00348-01} `procedure_specification` ::= 4.1/2
procedure defining_program_unit_name parameter_profile

{AI95-00348-01} `function_specification` ::= 4.2/2
function defining_designator parameter_and_result_profile

`designator` ::= [parent_unit_name .]identifier | operator_symbol 5

`defining_designator` ::= defining_program_unit_name | defining_operator_symbol 6

`defining_program_unit_name` ::= [parent_unit_name .]defining_identifier 7

[The optional `parent_unit_name` is only allowed for library units (see 10.1.1).] 8

`operator_symbol` ::= string_literal 9

{AI95-00395-01} {AI05-0299-1} The sequence of characters in an `operator_symbol` shall form a reserved word, a delimiter, or compound delimiter that corresponds to an operator belonging to one of the six categories of operators defined in subclause 4.5. 10/3

- 10.a/3 **Reason:** {AI95-00395-01} {AI05-0090-1} The “sequence of characters” of the string literal of the operator is a technical term (see 2.6), and does not include the surrounding quote characters. As defined in 2.2, lexical elements are “formed” from a sequence of characters. Spaces are not allowed, and upper and lower case is not significant.
- 11 defining_operator_symbol ::= operator_symbol
- 12 parameter_profile ::= [formal_part]
- 13/2 {AI95-00231-01} {AI95-00318-02} parameter_and_result_profile ::=
 [formal_part] **return** [null_exclusion] subtype_mark
 | [formal_part] **return** access_definition
- 14 formal_part ::=
 (parameter_specification {; parameter_specification})
- 15/3 {AI95-00231-01} {AI05-0142-4} parameter_specification ::=
 defining_identifier_list : [aliased] mode [null_exclusion] subtype_mark [:= default_expression]
 | defining_identifier_list : access_definition [:= default_expression]
- 16 mode ::= [**in**] | **in out** | **out**

Name Resolution Rules

- 17 A *formal parameter* is an object [directly visible within a subprogram_body] that represents the actual parameter passed to the subprogram in a call; it is declared by a parameter_specification. For a formal parameter, the expected type for its default_expression, if any, is that of the formal parameter.

Legality Rules

- 18/3 {AI05-0143-1} The *parameter mode* of a formal parameter conveys the direction of information transfer with the actual parameter: **in**, **in out**, or **out**. Mode **in** is the default, and is the mode of a parameter defined by an access_definition.
- 18.a/3 *This paragraph was deleted.* {AI05-0143-1}
- 19 A default_expression is only allowed in a parameter_specification for a formal parameter of mode **in**.
- 20/3 {AI95-00348-01} {AI05-0177-1} {AI05-0229-1} A subprogram_declaration or a generic_subprogram_declaration requires a completion [unless the Import aspect (see B.1) is True for the declaration; the completion shall be a body or a renaming_declaration (see 8.5)]. [A completion is not allowed for an abstract_subprogram_declaration (see 3.9.3), a null_procedure_declaration (see 6.7), or an expression_function_declaration (see 6.8).]
- 20.a/3 **Ramification:** {AI95-00348-01} {AI05-0177-1} Abstract subprograms, null procedures, and expression functions are not declared by subprogram_declarations, and so do not require completion (although the latter two can be completions). Protected subprograms are declared by subprogram_declarations, and so require completion. Note that an abstract subprogram is a subprogram, a null procedure is a subprogram, an expression function is a subprogram, and a protected subprogram is a subprogram, but a generic subprogram is not a subprogram.
- 20.b/3 **Proof:** {AI05-0229-1} When the Import aspect is True for any entity, no completion is allowed (see B.1).
- 21 A name that denotes a formal parameter is not allowed within the formal_part in which it is declared, nor within the formal_part of a corresponding body or accept_statement.
- 21.a **Ramification:** By contrast, generic_formal_parameter_declarations are visible to subsequent declarations in the same generic_formal_part.

Static Semantics

- 22 The *profile* of (a view of) a callable entity is either a parameter_profile or parameter_and_result_profile; it embodies information about the interface to that entity — for example, the profile includes information about parameters passed to the callable entity. All callable entities have a profile — enumeration literals, other subprograms, and entries. An access-to-subprogram type has a designated profile.] Associated with a profile is a calling convention. A subprogram_declaration

declares a procedure or a function, as indicated by the initial reserved word, with name and profile as given by its specification.

{AI95-00231-01} {AI95-00318-02} The nominal subtype of a formal parameter is the subtype determined by the optional `null_exclusion` and the `subtype_mark`, or defined by the `access_definition`, in the `parameter_specification`. The nominal subtype of a function result is the subtype determined by the optional `null_exclusion` and the `subtype_mark`, or defined by the `access_definition`, in the `parameter_and_result_profile`. 23/2

{AI05-0142-4} An *explicitly aliased parameter* is a formal parameter whose `parameter_specification` includes the reserved word **aliased**. 23.1/3

{AI95-00231-01} {AI95-00254-01} {AI95-00318-02} An *access parameter* is a formal **in** parameter specified by an `access_definition`. An *access result type* is a function result type specified by an `access_definition`. An access parameter or result type is of an anonymous access type (see 3.10). [Access parameters of an access-to-object type allow dispatching calls to be controlled by access values. Access parameters of an access-to-subprogram type permit calls to subprograms passed as parameters irrespective of their accessibility level.] 24/2

Discussion: {AI95-00318-02} Access result types have normal accessibility and thus don't have any special properties worth noting here. 24.a/2

The *subtypes of a profile* are: 25

- For any non-access parameters, the nominal subtype of the parameter. 26
- {AI95-00254-01} For any access parameters of an access-to-object type, the designated subtype of the parameter type. 27/2
- {AI95-00254-01} {AI05-0164-1} For any access parameters of an access-to-subprogram type, the subtypes of the designated profile of the parameter type. 27.1/3
- {AI95-00231-01} {AI95-00318-02} For any non-access result, the nominal subtype of the function result. 28/2
- {AI95-00318-02} For any access result type of an access-to-object type, the designated subtype of the result type. 28.1/2
- {AI95-00318-02} {AI05-0164-1} For any access result type of an access-to-subprogram type, the subtypes of the designated profile of the result type. 28.2/3

[The *types of a profile* are the types of those subtypes.] 29

{AI95-00348-01} {AI05-0177-1} [A subprogram declared by an `abstract_subprogram_declaration` is abstract; a subprogram declared by a `subprogram_declaration` is not. See 3.9.3, “Abstract Types and Subprograms”. Similarly, a procedure declared by a `null_procedure_declaration` is a null procedure; a procedure declared by a `subprogram_declaration` is not. See 6.7, “Null Procedures”. Finally, a function declared by an `expression_function_declaration` is an expression function; a function declared by a `subprogram_declaration` is not. See 6.8, “Expression Functions”.] 30/3

{AI95-00218-03} [An `overriding_indicator` is used to indicate whether overriding is intended. See 8.3.1, “Overriding Indicators”.] 30.1/2

Dynamic Semantics

{AI95-00348-01} The elaboration of a `subprogram_declaration` has no effect. 31/2

NOTES

- 1 A `parameter_specification` with several identifiers is equivalent to a sequence of single `parameter_specifications`, as explained in 3.3. 32

- 33 2 Abstract subprograms do not have bodies, and cannot be used in a nondispatching call (see 3.9.3, “Abstract Types and Subprograms”).
- 34 3 The evaluation of `default_expressions` is caused by certain calls, as described in 6.4.1. They are not evaluated during the elaboration of the subprogram declaration.
- 35 4 Subprograms can be called recursively and can be called concurrently from multiple tasks.

*Examples*36 *Examples of subprogram declarations:*

```

37 procedure Traverse_Tree;
procedure Increment(X : in out Integer);
procedure Right_Indent(Margin : out Line_Size);           -- see 3.5.4
procedure Switch(From, To : in out Link);               -- see 3.10.1
38 function Random return Probability;                   -- see 3.5.7
39 function Min_Cell(X : Link) return Cell;              -- see 3.10.1
function Next_Frame(K : Positive) return Frame;        -- see 3.10
function Dot_Product(Left, Right : Vector) return Real; -- see 3.6
40 function "*" (Left, Right : Matrix) return Matrix;    -- see 3.6

```

41 *Examples of **in** parameters with default expressions:*

```

42 procedure Print_Header(Pages : in Natural;
    Header : in Line := (1 .. Line'Last => ' '); -- see 3.6
    Center : in Boolean := True);

```

Extensions to Ada 83

- 42.a The syntax for `abstract_subprogram_declaration` is added. The syntax for `parameter_specification` is revised to allow for access parameters (see 3.10)
- 42.b/3 {AI05-0299-1} Program units that are library units may have a `parent_unit_name` to indicate the parent of a child (see 10.1.1).

Wording Changes from Ada 83

- 42.c We have incorporated the rules from RM83-6.5, “Function Subprograms” here and in 6.3, “Subprogram Bodies”
- 42.d We have incorporated the definitions of RM83-6.6, “Parameter and Result Type Profile - Overloading of Subprograms” here.
- 42.e The syntax rule for `defining_operator_symbol` is new. It is used for the defining occurrence of an `operator_symbol`, analogously to `defining_identifier`. Usage occurrences use the `direct_name` or `selector_name` syntactic categories. The syntax rules for `defining_designator` and `defining_program_unit_name` are new.

Extensions to Ada 95

- 42.f/2 {AI95-00218-03} Subprograms now allow `overriding_indicators` for better error checking of overriding.
- 42.g/2 {AI95-00231-01} An optional `null_exclusion` can be used in a formal parameter declaration. Similarly, an optional `null_exclusion` can be used in a function result.
- 42.h/2 {AI95-00318-02} The return type of a function can be an anonymous access type.

Wording Changes from Ada 95

- 42.i/2 {AI95-00254-01} A description of the purpose of anonymous access-to-subprogram parameters and the definition of the profile of subprograms containing them was added.
- 42.j/2 {AI95-00348-01} Split the production for `subprogram_specification` in order to make the declaration of null procedures (see 6.7) easier.
- 42.k/2 {AI95-00348-01} Moved the Syntax and Dynamic Semantics for `abstract_subprogram_declaration` to 3.9.3, so that the syntax and semantics are together. This also keeps abstract and null subprograms similar.
- 42.l/2 {AI95-00395-01} Revised to allow `other_format` characters in `operator_symbols` in the same way as the underlying constructs.

Extensions to Ada 2005

- {AI05-0142-4} Parameters can now be explicitly aliased, allowing parts of function results to designate parameters and forcing by-reference parameter passing. 42.m/3
- {AI05-0143-1} The parameters of a function can now have any mode. 42.n/3
- {AI05-0183-1} An optional `aspect_specification` can be used in a `subprogram_declaration`. This is described in 13.1.1. 42.o/3

Wording Changes from Ada 2005

- {AI05-0177-1} Added expression functions (see 6.8) to the wording. 42.p/3

6.1.1 Preconditions and Postconditions

{AI05-0145-2} {AI05-0247-1} For a subprogram or entry, the following language-defined aspects may be specified with an `aspect_specification` (see 13.1.1): 1/3

Pre This aspect specifies a specific precondition for a callable entity; it shall be specified by an **expression**, called a *specific precondition expression*. If not specified for an entity, the specific precondition expression for the entity is the enumeration literal `True`. 2/3

To be honest: In this and the following rules, we are talking about the enumeration literal `True` declared in package `Standard` (see A.1), and not some other value or identifier `True`. That matters as some rules depend on full conformance of these expressions, which depends on the specific declarations involved. 2.a/3

Aspect Description for Pre: Precondition; a condition that must hold true before a call. 2.b/3

{AI05-0254-1} {AI05-0262-1} **Pre'Class** 3/3

This aspect specifies a class-wide precondition for an operation of a tagged type and its descendants; it shall be specified by an **expression**, called a *class-wide precondition expression*. If not specified for an entity, then if no other class-wide precondition applies to the entity, the class-wide precondition expression for the entity is the enumeration literal `True`.

Ramification: {AI05-0254-1} If other class-wide preconditions apply to the entity and no class-wide precondition is specified, no class-wide precondition is defined for the entity; of course, the class-wide preconditions (of ancestors) that apply are still going to be checked. We need subprograms that don't have ancestors and don't specify a class-wide precondition to have a class-wide precondition of `True`, so that adding such a precondition to a descendant has no effect (necessary as a dispatching call through the root routine would not check any precondition). 3.a/3

Aspect Description for Pre'Class: Precondition inherited on type derivation. 3.b/3

Post This aspect specifies a specific postcondition for a callable entity; it shall be specified by an **expression**, called a *specific postcondition expression*. If not specified for an entity, the specific postcondition expression for the entity is the enumeration literal `True`. 4/3

Aspect Description for Post: Postcondition; a condition that must hold true after a call. 4.a/3

{AI05-0262-1} **Post'Class** 5/3

This aspect specifies a class-wide postcondition for an operation of a tagged type and its descendants; it shall be specified by an **expression**, called a *class-wide postcondition expression*. If not specified for an entity, the class-wide postcondition expression for the entity is the enumeration literal `True`.

Aspect Description for Post'Class: Postcondition inherited on type derivation. 5.a/3

Name Resolution Rules

{AI05-0145-2} The expected type for a precondition or postcondition expression is any boolean type. 6/3

{AI05-0145-2} {AI05-0262-1} Within the expression for a `Pre'Class` or `Post'Class` aspect for a primitive subprogram of a tagged type *T*, a name that denotes a formal parameter of type *T* is interpreted as having type *T*`Class`. Similarly, a name that denotes a formal access parameter of type `access-to-T` is interpreted

as having type access-to-*T*Class. [This ensures that the expression is well-defined for a primitive subprogram of a type descended from *T*.]

- 8/3 {AI05-0145-2} {AI05-0264-1} For an attribute_reference with attribute_designator Old, if the attribute reference has an expected type or shall resolve to a given type, the same applies to the prefix; otherwise, the prefix shall be resolved independently of context.

Legality Rules

- 9/3 {AI05-0145-2} {AI05-0230-1} The Pre or Post aspect shall not be specified for an abstract subprogram or a null procedure. [Only the Pre'Class and Post'Class aspects may be specified for such a subprogram.]
- 9.a/3 **Discussion:** {AI05-0183-1} Pre'Class and Post'Class can only be specified on primitive routines of tagged types, by a blanket rule found in 13.1.1.
- 10/3 {AI05-0247-1} {AI05-0254-1} If a type *T* has an implicitly declared subprogram *P* inherited from a parent type *T1* and a homograph (see 8.3) of *P* from a progenitor type *T2*, and
- 11/3 • the corresponding primitive subprogram *P1* of type *T1* is neither null nor abstract; and
- 12/3 • the class-wide precondition expression True does not apply to *P1* (implicitly or explicitly); and
- 13/3 • there is a class-wide precondition expression that applies to the corresponding primitive subprogram *P2* of *T2* that does not fully conform to any class-wide precondition expression that applies to *P1*,
- 14/3 {AI05-0247-1} {AI05-0254-1} then:
- 15/3 • If the type *T* is abstract, the implicitly declared subprogram *P* is *abstract*.
- 16/3 • Otherwise, the subprogram *P* *requires overriding* and shall be overridden with a nonabstract subprogram.
- 16.a/3 **Discussion:** We use the term "requires overriding" here so that this rule is taken into account when calculating visibility in 8.3; otherwise we would have a mess when this routine is overridden.
- 16.b/3 **Reason:** Such an inherited subprogram would necessarily violate the Liskov Substitutability Principle (LSP) if called via a dispatching call from an ancestor other than the one that provides the called body. In such a case, the class-wide precondition of the actual body is stronger than the class-wide precondition of the ancestor. If we did not enforce that precondition for the body, the body could be called when the precondition it knows about is False — such "counterfeiting" of preconditions has to be avoided. But enforcing the precondition violates LSP. We do not want the language to be implicitly creating bodies that violate LSP; the programmer can still write an explicit body that calls the appropriate parent subprogram. In that case, the violation of LSP is explicitly in the code and obvious to code reviewers (both human and automated).
- 16.c/3 We have to say that the subprogram is abstract for an abstract type in this case, so that the next concrete type has to override it for the reasons above. Otherwise, inserting an extra level of abstract types would eliminate the requirement to override (as there is only one declared operation for the concrete type), and that would be bad for the reasons given above.
- 16.d/3 **Ramification:** This requires the set of class-wide preconditions that apply to the interface routine to be strictly stronger than those that apply to the concrete routine. Since full conformance requires each name to denote the same declaration, it is unlikely that independently declared preconditions would conform. This rule does allow "diamond inheritance" of preconditions, and of course no preconditions at all match.
- 16.e/3 We considered adopting a rule that would allow examples where the expressions would conform after all inheritance has been applied, but this is complex and is not likely to be common in practice. Since the penalty here is just that an explicit overriding is required, the complexity is too much.
- 17/3 {AI05-0247-1} If a renaming of a subprogram or entry *S1* overrides an inherited subprogram *S2*, then the overriding is illegal unless each class-wide precondition expression that applies to *S1* fully conforms to some class-wide precondition expression that applies to *S2* and each class-wide precondition expression that applies to *S2* fully conforms to some class-wide precondition expression that applies to *S1*.
- 17.a/3 **Reason:** Such an overriding subprogram would violate LSP, as the precondition of *S1* would usually be different (and thus stronger) than the one known to a dispatching call through an ancestor routine of *S2*. This is always OK if the preconditions match, so we always allow that.

Ramification: This only applies to primitives of tagged types; other routines cannot have class-wide preconditions.	17.b/3
<i>Static Semantics</i>	
{AI05-0145-2} If a Pre'Class or Post'Class aspect is specified for a primitive subprogram of a tagged type <i>T</i> , then the associated expression also applies to the corresponding primitive subprogram of each descendant of <i>T</i> .	18/3
{AI05-0145-2} {AI05-0262-1} {AI05-0290-1} If performing checks is required by the Pre, Pre'Class, Post, or Post'Class assertion policies (see 11.4.2) in effect at the point of a corresponding aspect specification applicable to a given subprogram or entry, then the respective precondition or postcondition expressions are considered <i>enabled</i> .	19/3
Ramification: {AI05-0290-1} If a class-wide precondition or postcondition expression is enabled, it remains enabled when inherited by an overriding subprogram, even if the policy in effect is Ignore for the inheriting subprogram.	19.a/3
{AI05-0273-1} An expression is <i>potentially unevaluated</i> if it occurs within:	20/3
<ul style="list-style-type: none"> • any part of an <i>if_expression</i> other than the first condition; 	21/3
<ul style="list-style-type: none"> • a <i>dependent_expression</i> of a <i>case_expression</i>; 	22/3
<ul style="list-style-type: none"> • the right operand of a short-circuit control form; or 	23/3
<ul style="list-style-type: none"> • a <i>membership_choice</i> other than the first of a membership operation. 	24/3
{AI05-0145-2} For a prefix <i>X</i> that denotes an object of a nonlimited type, the following attribute is defined:	25/3
X'Old {AI05-0145-2} {AI05-0262-1} {AI05-0273-1} For each X'Old in a postcondition expression that is enabled, a constant is implicitly declared at the beginning of the subprogram or entry. The constant is of the type of <i>X</i> and is initialized to the result of evaluating <i>X</i> (as an expression) at the point of the constant declaration. The value of X'Old in the postcondition expression is the value of this constant; the type of X'Old is the type of <i>X</i> . These implicit constant declarations occur in an arbitrary order.	26/3
{AI05-0145-2} {AI05-0262-1} {AI05-0273-1} Reference to this attribute is only allowed within a postcondition expression. The prefix of an Old attribute_reference shall not contain a Result attribute_reference, nor an Old attribute_reference, nor a use of an entity declared within the postcondition expression but not within prefix itself (for example, the loop parameter of an enclosing quantified_expression). The prefix of an Old attribute_reference that is potentially unevaluated shall statically denote an entity.	27/3
Discussion: The prefix <i>X</i> can be any nonlimited object that obeys the syntax for prefix other than the few exceptions given above (discussed below). Useful cases are: the <i>name</i> of a formal parameter of mode [in] out, the <i>name</i> of a global variable updated by the subprogram, a function call passing those as parameters, a subcomponent of those things, etc.	27.a/3
A qualified expression can be used to make an arbitrary expression into a valid prefix, so T'(X + Y)'Old is legal, even though (X + Y)'Old is not. The value being saved here is the sum of <i>X</i> and <i>Y</i> (a function result is an object). Of course, in this case "+"(X, Y)'Old is also legal, but the qualified expression is arguably more readable.	27.b/3
Note that F(X)'Old and F(X'Old) are not necessarily equal. The former calls F(X) and saves that value for later use during the postcondition. The latter saves the value of <i>X</i> , and during the postcondition, passes that saved value to <i>F</i> . In most cases, the former is what one wants (but it is not always legal, see below).	27.c/3
If <i>X</i> has controlled parts, adjustment and finalization are implied by the implicit constant declaration.	27.d/3
If postconditions are disabled, we want the compiler to avoid any overhead associated with saving 'Old values.	27.e/3
'Old makes no sense for limited types, because its implementation involves copying. It might make semantic sense to allow build-in-place, but it's not worth the trouble.	27.f/3
Reason: {AI05-0273-1} Since the prefix is evaluated unconditionally when the subprogram is called, we cannot allow it to include values that do not exist at that time (like 'Result and loop parameters of quantified_expressions). We also do not allow it to include 'Old references, as those would be redundant (the entire prefix is evaluated when the	27.g/3

subprogram is called), and allowing them would require some sort of order to the implicit constant declarations (because in A(I'Old)'Old, we surely would want the value of I'Old evaluated before the A(I'Old) is evaluated).

27.h/3 {AI05-0273-1} In addition, we only allow simple names as the prefix of the Old attribute if the `attribute_reference` might not be evaluated when the postcondition expression is evaluated. This is necessary because the Old prefixes have to be unconditionally evaluated when the subprogram is called; the compiler cannot in general know whether they will be needed in the postcondition expression. To see the problem, consider:

```
27.i/3   Table : array (1..10) of Integer := ...
        procedure Bar (I : in out Natural)
            with Post => I > 0 and then Table(I)'Old = 1; -- Illegal
```

27.j/3 In this example, the compiler cannot know the value of I when the subprogram returns (since the subprogram execution can change it), and thus it does not know whether Table(I)'Old will be needed then. Thus it has to always create an implicit constant and evaluate Table(I) when Bar is called (because not having the value when it is needed is not acceptable). But if I = 0 when the subprogram is called, that evaluation will raise `Constraint_Error`, and that will happen even if I is unchanged by the subprogram and the value of Table(I)'Old is not ultimately needed. It's easy to see how a similar problem could occur for a dereference of an access type. This would be mystifying (since the point of the short circuit is to eliminate this possibility, but it cannot do so). Therefore, we require the prefix of any Old attribute in such a context to statically denote an object, which eliminates anything that could change at during execution.

27.k/3 It is easy to work around most errors that occur because of this rule. Just move the 'Old to the outer object, before any indexing, dereferences, or components. (That does not work for function calls, however, nor does it work for array indexing if the index can change during the execution of the subprogram.)

28/3 {AI05-0145-2} For a prefix F that denotes a function declaration, the following attribute is defined:

29/3 F'Result {AI05-0145-2} {AI05-0262-1} Within a postcondition expression for function F, denotes the result object of the function. The type of this attribute is that of the function result except within a Post'Class postcondition expression for a function with a controlling result or with a controlling access result. For a controlling result, the type of the attribute is *T*Class, where *T* is the function result type. For a controlling access result, the type of the attribute is an anonymous access type whose designated type is *T*Class, where *T* is the designated type of the function result type.

30/3 {AI05-0262-1} Use of this attribute is allowed only within a postcondition expression for F.

Dynamic Semantics

31/3 {AI05-0145-2} {AI05-0247-1} {AI05-0290-1} Upon a call of the subprogram or entry, after evaluating any actual parameters, precondition checks are performed as follows:

- 32/3 • The specific precondition check begins with the evaluation of the specific precondition expression that applies to the subprogram or entry, if it is enabled; if the expression evaluates to False, `Assertions.Assertion_Error` is raised; if the expression is not enabled, the check succeeds.
- 33/3 • The class-wide precondition check begins with the evaluation of any enabled class-wide precondition expressions that apply to the subprogram or entry. If and only if all the class-wide precondition expressions evaluate to False, `Assertions.Assertion_Error` is raised.

33.a/3 **Ramification:** The class-wide precondition expressions of the entity itself as well as those of any parent or progenitor operations are evaluated, as these expressions apply to the corresponding operations of all descendants.

33.b/3 Class-wide precondition checks are performed for all appropriate calls, but only enabled precondition expressions are evaluated. Thus, the check would be trivial if no precondition expressions are enabled.

34/3 {AI05-0145-2} {AI05-0247-1} {AI05-0254-1} {AI05-0269-1} The precondition checks are performed in an arbitrary order, and if any of the class-wide precondition expressions evaluate to True, it is not specified whether the other class-wide precondition expressions are evaluated. The precondition checks and any check for elaboration of the subprogram body are performed in an arbitrary order. It is not specified whether in a call on a protected operation, the checks are performed before or after starting the protected action. For an entry call, the checks are performed prior to checking whether the entry is open.

34.a/3 **Reason:** We need to explicitly allow short-circuiting of the evaluation of the class-wide precondition check if any expression fails, as it consists of multiple expressions; we don't need a similar permission for the specific precondition

- check as it consists only of a single expression. Nothing is evaluated for the call after a check fails, as the failed check propagates an exception.
- {AI05-0145-2} {AI05-0247-1} {AI05-0254-1} {AI05-0262-1} {AI05-0290-1} Upon successful return from a call of the subprogram or entry, prior to copying back any by-copy **in out** or **out** parameters, the postcondition check is performed. This consists of the evaluation of any enabled specific and class-wide postcondition expressions that apply to the subprogram or entry. If any of the postcondition expressions evaluate to False, then `Assertions.Assertion_Error` is raised. The postcondition expressions are evaluated in an arbitrary order, and if any postcondition expression evaluates to False, it is not specified whether any other postcondition expressions are evaluated. The postcondition check, and any constraint or predicate checks associated with **in out** or **out** parameters are performed in an arbitrary order. 35/3
- Ramification:** The class-wide postcondition expressions of the entity itself as well as those of any parent or progenitor operations are evaluated, as these apply to all descendants; in contrast, only the specific postcondition of the entity applies. Postconditions can always be evaluated inside the invoked body. 35.a/3
- {AI05-0145-2} {AI05-0262-1} If a precondition or postcondition check fails, the exception is raised at the point of the call; the exception cannot be handled inside the called subprogram or entry]. Similarly, any exception raised by the evaluation of a precondition or postcondition expression is raised at the point of call. 36/3
- {AI05-0145-2} {AI05-0247-1} {AI05-0254-1} {AI05-0262-1} For any subprogram or entry call (including dispatching calls), the checks that are performed to verify specific precondition expressions and specific and class-wide postcondition expressions are determined by those for the subprogram or entry actually invoked. Note that the class-wide postcondition expressions verified by the postcondition check that is part of a call on a primitive subprogram of type *T* includes all class-wide postcondition expressions originating in any progenitor of *T*, even if the primitive subprogram called is inherited from a type *TI* and some of the postcondition expressions do not apply to the corresponding primitive subprogram of *TI*. 37/3
- Ramification:** This applies to access-to-subprogram calls, dispatching calls, and to statically bound calls. We need this rule to cover statically bound calls as well, as specific pre- and postconditions are not inherited, but the subprogram might be. 37.a/3
- For concrete subprograms, we require the original specific postcondition to be evaluated as well as the inherited class-wide postconditions in order that the semantics of an explicitly defined wrapper that does nothing but call the original subprogram is the same as that of an inherited subprogram. 37.b/3
- Note that this rule does not apply to class-wide preconditions; they have their own rules mentioned below. 37.c/3
- {AI05-0145-2} {AI05-0247-1} {AI05-0254-1} The class-wide precondition check for a call to a subprogram or entry consists solely of checking the class-wide precondition expressions that apply to the denoted callable entity (not necessarily the one that is invoked). 38/3
- Ramification:** For a dispatching call, we are talking about the `Pre'Class(es)` that apply to the subprogram that the dispatching call is resolving to, not the `Pre'Class(es)` for the subprogram that is ultimately dispatched to. The class-wide precondition of the resolved call is necessarily the same or stronger than that of the invoked call. For a statically bound call, these are the same; for an access-to-subprogram, (which has no class-wide preconditions of its own), we check the class-wide preconditions of the invoked routine. 38.a/3
- Implementation Note:** These rules imply that logically, class-wide preconditions of routines must be checked at the point of call (other than for access-to-subprogram calls, which must be checked in the body, probably using a wrapper). Specific preconditions that might be called with a dispatching call or via an access-to-subprogram value must be checked inside of the subprogram body. In contrast, the postcondition checks always need to be checked inside the body of the routine. Of course, an implementation can evaluate all of these at the point of call for statically bound calls if the implementation uses wrappers for dispatching bodies and for 'Access values. 38.b/3
- There is no requirement for an implementation to generate special code for routines that are imported from outside of the Ada program. That's because there is a requirement on the programmer that the use of interfacing aspects do not violate Ada semantics (see B.1). That includes making pre- and postcondition checks. For instance, if the implementation expects routines to make their own postcondition checks in the body before returning, C code can be assumed to do this (even though that is highly unlikely). That's even though the formal definition of those checks is that they are evaluated at the call site. Note that pre- and postconditions can be very useful for verification tools (even 38.c/3

if they aren't checked), because they tell the tool about the expectations on the foreign code that it most likely cannot analyze.

39/3 {AI05-0145-2} {AI05-0247-1} {AI05-0254-1} For a call via an access-to-subprogram value, all precondition and postcondition checks performed are determined by the subprogram or entry denoted by the prefix of the Access attribute reference that produced the value.

NOTES

40/3 5 {AI05-0145-2} {AI05-0262-1} A precondition is checked just before the call. If another task can change any value that the precondition expression depends on, the precondition need not hold within the subprogram or entry body.

Extensions to Ada 2005

40.a/3 {AI05-0145-2} {AI05-0230-1} {AI05-0247-1} {AI05-0254-1} {AI05-0262-1} {AI05-0273-1} {AI05-0274-1} Pre and Post aspects are new.

6.2 Formal Parameter Modes

1 [A parameter_specification declares a formal parameter of mode **in**, **in out**, or **out**.]

Static Semantics

2 A parameter is passed either *by copy* or *by reference*. [When a parameter is passed by copy, the formal parameter denotes a separate object from the actual parameter, and any information transfer between the two occurs only before and after executing the subprogram. When a parameter is passed by reference, the formal parameter denotes (a view of) the object denoted by the actual parameter; reads and updates of the formal parameter directly reference the actual parameter object.]

3/3 {AI05-0142-4} {AI05-0262-1} A type is a *by-copy type* if it is an elementary type, or if it is a descendant of a private type whose full type is a by-copy type. A parameter of a by-copy type is passed by copy, unless the formal parameter is explicitly aliased.

4 A type is a *by-reference type* if it is a descendant of one of the following:

- 5 • a tagged type;
- 6 • a task or protected type;
- 7/3 • {AI05-0096-1} an explicitly limited record type;
- 7.a/3 *This paragraph was deleted.* {AI05-0096-1}
- 8 • a composite type with a subcomponent of a by-reference type;
- 9 • a private type whose full type is a by-reference type.

10/3 {AI05-0142-4} {AI05-0188-1} A parameter of a by-reference type is passed by reference, as is an explicitly aliased parameter of any type. Each value of a by-reference type has an associated object. For a parenthesized expression, qualified_expression, or type_conversion, this object is the one associated with the operand. For a conditional_expression, this object is the one associated with the evaluated *dependent_expression*.

10.a **Ramification:** By-reference parameter passing makes sense only if there is an object to reference; hence, we define such an object for each case.

10.b Since tagged types are by-reference types, this implies that every value of a tagged type has an associated object. This simplifies things, because we can define the tag to be a property of the object, and not of the value of the object, which makes it clearer that object tags never change.

10.c We considered simplifying things even more by making every value (and therefore every expression) have an associated object. After all, there is little semantic difference between a constant object and a value. However, this would cause problems for untagged types. In particular, we would have to do a constraint check on every read of a type conversion (or a renaming thereof) in certain cases.

- {AI95-00318-02} We do not want this definition to depend on the view of the type; privateness is essentially ignored for this definition. Otherwise, things would be confusing (does the rule apply at the call site, at the site of the declaration of the subprogram, at the site of the return statement?), and requiring different calls to use different mechanisms would be an implementation burden. 10.d/2
- C.6, “Shared Variable Control” says that a composite type with an atomic or volatile subcomponent is a by-reference type, among other things. 10.e
- Every value of a limited by-reference type is the value of one and only one limited object. The *associated object* of a value of a limited by-reference type is the object whose value it represents. Two values of a limited by-reference type are the *same* if and only if they represent the value of the same object. 10.f
- We say “by-reference” above because these statements are not always true for limited private types whose underlying type is nonlimited (unfortunately). 10.g
- {AI05-0240-1} For other parameters, it is unspecified whether the parameter is passed by copy or by reference. 11/3
- Discussion:** {AI05-0005-1} There is no need to incorporate the discussion of AI83-00178, which requires pass-by-copy for certain kinds of actual parameters, while allowing pass-by-reference for others. This is because we explicitly indicate that a function creates an anonymous constant object for its result (see 6.5). We also provide a special dispensation for instances of `Unchecked_Conversion` to return by reference (see 13.9). 11.a/3
- Bounded (Run-Time) Errors*
- {AI05-0240-1} If one **name** denotes a part of a formal parameter, and a second **name** denotes a part of a distinct formal parameter or an object that is not part of a formal parameter, then the two **names** are considered *distinct access paths*. If an object is of a type for which the parameter passing mechanism is not specified and is not an explicitly aliased parameter, then it is a bounded error to assign to the object via one access path, and then read the value of the object via a distinct access path, unless the first access path denotes a part of a formal parameter that no longer exists at the point of the second access [(due to leaving the corresponding callable construct).] The possible consequences are that `Program_Error` is raised, or the newly assigned value is read, or some old value of the object is read. 12/3
- Discussion:** For example, if we call “P(X => Global_Variable, Y => Global_Variable)”, then within P, the names “X”, “Y”, and “Global_Variable” are all distinct access paths. If `Global_Variable`'s type is neither pass-by-copy nor pass-by-reference, then it is a bounded error to assign to `Global_Variable` and then read X or Y, since the language does not specify whether the old or the new value would be read. On the other hand, if `Global_Variable`'s type is pass-by-copy, then the old value would always be read, and there is no error. Similarly, if `Global_Variable`'s type is defined by the language to be pass-by-reference, then the new value would always be read, and again there is no error. 12.a
- Reason:** We are saying *assign* here, not *update*, because updating any subcomponent is considered to update the enclosing object. 12.b
- The “still exists” part is so that a read after the subprogram returns is OK. 12.c
- If the parameter is of a by-copy type, then there is no issue here — the formal is not a view of the actual. If the parameter is of a by-reference type, then the programmer may depend on updates through one access path being visible through some other access path, just as if the parameter were of an access type. 12.d
- Implementation Note:** The implementation can keep a copy in a register of a parameter whose parameter-passing mechanism is not specified. If a different access path is used to update the object (creating a bounded error situation), then the implementation can still use the value of the register, even though the in-memory version of the object has been changed. However, to keep the error properly bounded, if the implementation chooses to read the in-memory version, it has to be consistent -- it cannot then assume that something it has proven about the register is true of the memory location. For example, suppose the formal parameter is L, the value of L(6) is now in a register, and L(6) is used in an `indexed_component` as in “A(L(6)) := 99;”, where A has bounds 1..3. If the implementation can prove that the value for L(6) in the register is in the range 1..3, then it need not perform the constraint check if it uses the register value. However, if the memory value of L(6) has been changed to 4, and the implementation uses that memory value, then it had better not alter memory outside of A. 12.e
- Note that the rule allows the implementation to pass a parameter by reference and then keep just part of it in a register, or, equivalently, to pass part of the parameter by reference and another part by copy. 12.f
- Reason:** We do not want to go so far as to say that the mere presence of aliasing is wrong. We wish to be able to write the following sorts of things in standard Ada: 12.g

12.h

```

procedure Move ( Source : in String;
                Target : out String;
                Drop   : in Truncation := Error;
                Justify : in Alignment  := Left;
                Pad    : in Character  := Space);
    -- Copies elements from Source to Target (safely if they overlap)

```

12.i This is from the standard string handling package. It would be embarrassing if this couldn't be written in Ada!

12.j The “then” before “read” in the rule implies that the implementation can move a read to an earlier place in the code, but not to a later place after a potentially aliased assignment. Thus, if the subprogram reads one of its parameters into a local variable, and then updates another potentially aliased one, the local copy is safe — it is known to have the old value. For example, the above-mentioned Move subprogram can be implemented by copying Source into a local variable before assigning into Target.

12.k For an `assignment_statement` assigning one array parameter to another, the implementation has to check which direction to copy at run time, in general, in case the actual parameters are overlapping slices. For example:

12.l

```

procedure Copy(X : in out String; Y: String) is
begin
    X := Y;
end Copy;

```

12.m It would be wrong for the compiler to assume that X and Y do not overlap (unless, of course, it can prove otherwise).

NOTES

13 6 A formal parameter of mode `in` is a constant view (see 3.3); it cannot be updated within the `subprogram_body`.

Extensions to Ada 83

13.a The value of an `out` parameter may be read. An `out` parameter is treated like a declared variable without an explicit initial expression.

Wording Changes from Ada 83

13.b Discussion of copy-in for parts of out parameters is now covered in 6.4.1, “Parameter Associations”.

13.c The concept of a by-reference type is new to Ada 95.

13.d We now cover in a general way in 3.7.2 the rule regarding erroneous execution when a discriminant is changed and one of the parameters depends on the discriminant.

Wording Changes from Ada 2005

13.e/3 {AI05-0096-1} **Correction:** Corrected so that limited derived types are by-reference only if their parent is.

13.f/3 {AI05-0142-4} Defined that explicitly aliased parameters (see 6.1) are always passed by reference.

6.3 Subprogram Bodies

1 [A `subprogram_body` specifies the execution of a subprogram.]

Syntax

2/3

```

{AI95-00218-03} {AI05-0183-1} subprogram_body ::=
    [overriding_indicator]
    subprogram_specification
    [aspect_specification] is
    declarative_part
begin
    handled_sequence_of_statements
end [designator];

```

3 If a designator appears at the end of a `subprogram_body`, it shall repeat the `defining_designator` of the `subprogram_specification`.

Legality Rules

[In contrast to other bodies,] a `subprogram_body` need not be the completion of a previous declaration[, 4
in which case the body declares the subprogram]. If the body is a completion, it shall be the completion of
a `subprogram_declaration` or `generic_subprogram_declaration`. The profile of a `subprogram_body`
that completes a declaration shall conform fully to that of the declaration.

Static Semantics

A `subprogram_body` is considered a declaration. It can either complete a previous declaration, or itself 5
be the initial declaration of the subprogram.

Dynamic Semantics

The elaboration of a nongeneric `subprogram_body` has no other effect than to establish that the 6
subprogram can from then on be called without failing the `Elaboration_Check`.

Ramification: See 12.2 for elaboration of a generic body. Note that protected `subprogram_bodies` never get 6.a
elaborated; the elaboration of the containing `protected_body` allows them to be called without failing the
`Elaboration_Check`.

[The execution of a `subprogram_body` is invoked by a subprogram call.] For this execution the 7
`declarative_part` is elaborated, and the `handled_sequence_of_statements` is then executed.

Examples

Example of procedure body: 8

```

procedure Push(E : in Element_Type; S : in out Stack) is 9
begin
  if S.Index = S.Size then
    raise Stack_Overflow;
  else
    S.Index := S.Index + 1;
    S.Space(S.Index) := E;
  end if;
end Push;

```

Example of a function body: 10

```

function Dot_Product(Left, Right : Vector) return Real is 11
  Sum : Real := 0.0;
begin
  Check(Left'First = Right'First and Left'Last = Right'Last);
  for J in Left'Range loop
    Sum := Sum + Left(J)*Right(J);
  end loop;
  return Sum;
end Dot_Product;

```

Extensions to Ada 83

A `renaming_declaration` may be used instead of a `subprogram_body`. 11.a

Wording Changes from Ada 83

The syntax rule for `subprogram_body` now uses the syntactic category `handled_sequence_of_statements`. 11.b

The `declarative_part` of a `subprogram_body` is now required; that doesn't make any real difference, because a 11.c
`declarative_part` can be empty.

We have incorporated some rules from RM83-6.5 here. 11.d

RM83 forgot to restrict the definition of elaboration of a `subprogram_body` to nongenerics. 11.e

Wording Changes from Ada 95

{A195-00218-03} `Overriding_indicator` is added to `subprogram_body`. 11.f/2

11.g/3 {AI05-0183-1} An optional `aspect_specification` can be used in a `subprogram_body`. This is described in 13.1.1.

6.3.1 Conformance Rules

1 [When subprogram profiles are given in more than one place, they are required to conform in one of four ways: type conformance, mode conformance, subtype conformance, or full conformance.]

Static Semantics

2/1 {8652/0011} {AI95-00117-01} [As explained in B.1, “Interfacing Aspects”, a *convention* can be specified for an entity.] Unless this International Standard states otherwise, the default convention of an entity is Ada. [For a callable entity or access-to-subprogram type, the convention is called the *calling convention*.] The following conventions are defined by the language:

3/3 • {AI05-0229-1} The default calling convention for any subprogram not listed below is *Ada*. [The Convention aspect may be specified to override the default calling convention (see B.1)].

3.a **Ramification:** See also the rule about renamings-as-body in 8.5.4.

4 • The *Intrinsic* calling convention represents subprograms that are “built in” to the compiler. The default calling convention is *Intrinsic* for the following:

- 5 • an enumeration literal;
- 6 • a `"/=` operator declared implicitly due to the declaration of `=` (see 6.6);
- 7 • any other implicitly declared subprogram unless it is a dispatching operation of a tagged type;
- 8 • an inherited subprogram of a generic formal tagged type with unknown discriminants;

8.a.1/1 **Reason:** Consider:

```
8.a.2/1 package P is
      type Root is tagged null record;
      procedure Proc(X: Root);
    end P;

8.a.3/1 generic
      type Formal(<>) is new Root with private;
    package G is
      ...
    end G;

8.a.4/1 package body G is
      ...
      X: Formal := ...;
      ...
      Proc(X); -- This is a dispatching call in Instance, because
               -- the actual type for Formal is class-wide.
      ...
      -- Proc'Access would be illegal here, because it is of
      -- convention Intrinsic, by the above rule.
    end G;

8.a.5/1 type Actual is new Root with ...;
      procedure Proc(X: Actual);
      package Instance is new G(Formal => Actual'Class);
      -- It is legal to pass in a class-wide actual, because Formal
      -- has unknown discriminants.
```

8.a.6/1 Within Instance, all calls to Proc will be dispatching calls, so Proc doesn't really exist in machine code, so we wish to avoid taking 'Access of it. This rule applies to those cases where the actual type might be class-wide, and makes these *Intrinsic*, thus forbidding 'Access.

- 9 • an attribute that is a subprogram;
- 10/2 • {AI95-00252-01} a subprogram declared immediately within a `protected_body`;
- 10.1/2 • {AI95-00252-01} {AI95-00407-01} any prefixed view of a subprogram (see 4.1.3).

- Reason:** The profile of a prefixed view is different than the “real” profile of the subprogram (it doesn't have the first parameter), so we don't want to be able to take 'Access of it, as that would require generating a wrapper of some sort. 10.a/2
- [The Access attribute is not allowed for Intrinsic subprograms.] 11
- Ramification:** The Intrinsic calling convention really represents any number of calling conventions at the machine code level; the compiler might have a different instruction sequence for each intrinsic. That's why the Access attribute is disallowed. We do not wish to require the implementation to generate an out of line body for an intrinsic. 11.a
- {AI05-0229-1} Whenever we wish to disallow the Access attribute in order to ease implementation, we make the subprogram Intrinsic. Several language-defined subprograms have “with Convention => Intrinsic;”. An implementation might actually implement this as “with Import => True, Convention => Intrinsic;”, if there is really no body, and the implementation of the subprogram is built into the code generator. 11.b/3
- Subprograms declared in `protected_bodies` will generally have a special calling convention so as to pass along the identification of the current instance of the protected type. The convention is not *protected* since such local subprograms need not contain any “locking” logic since they are not callable via “external” calls; this rule prevents an access value designating such a subprogram from being passed outside the protected unit. 11.c
- The “implicitly declared subprogram” above refers to predefined operators (other than the “=” of a tagged type) and the inherited subprograms of untagged types. 11.d
- The default calling convention is *protected* for a protected subprogram, and for an access-to-subprogram type with the reserved word **protected** in its definition. 12
 - The default calling convention is *entry* for an entry. 13
 - {AI95-00254-01} {AI95-00409-01} {AI05-0264-1} The calling convention for an anonymous access-to-subprogram parameter or anonymous access-to-subprogram result is *protected* if the reserved word **protected** appears in its definition; otherwise, it is the convention of the subprogram that contains the parameter. 13.1/3
 - Ramification:** The calling convention for other anonymous access-to-subprogram types is Ada. 13.a/2
 - {8652/0011} {AI95-00117-01} [If not specified above as Intrinsic, the calling convention for any inherited or overriding dispatching operation of a tagged type is that of the corresponding subprogram of the parent type.] The default calling convention for a new dispatching operation of a tagged type is the convention of the type. 13.2/1
 - Reason:** The first rule is officially stated in 3.9.2. The second is intended to make interfacing to foreign OOP languages easier, by making the default be that the type and operations all have the same convention. 13.a.1/1
- {AI05-0229-1} Of these four conventions, only Ada and Intrinsic are allowed as a *convention_identifier* in the specification of a Convention aspect. 14/3
- Discussion:** {AI05-0229-1} The names of the *protected* and *entry* calling conventions cannot be used in the specification of Convention. Note that **protected** and **entry** are reserved words. 14.a/3
- {AI95-00409-01} Two profiles are *type conformant* if they have the same number of parameters, and both have a result if either does, and corresponding parameter and result types are the same, or, for access parameters or access results, corresponding designated types are the same, or corresponding designated profiles are type conformant. 15/2
- Discussion:** {AI95-00409-01} For anonymous access-to-object parameters, the designated types have to be the same for type conformance, not the access types, since in general each access parameter has its own anonymous access type, created when the subprogram is called. Of course, corresponding parameters have to be either both access parameters or both not access parameters. 15.a/2
- {AI95-00409-01} Similarly, for anonymous access-to-subprogram parameters, the designated profiles of the types, not the types themselves, have to be conformant. 15.b/2
- {AI95-00318-02} {AI95-00409-01} {AI05-0142-4} Two profiles are *mode conformant* if: 16/3
- {AI05-0142-4} {AI05-0262-1} they are type conformant; and 16.1/3
 - {AI05-0142-4} corresponding parameters have identical modes and both or neither are explicitly aliased parameters; and 16.2/3

- 16.3/3 • *{AI05-0207-1}* for corresponding access parameters and any access result type, the designated subtypes statically match and either both or neither are access-to-constant, or the designated profiles are subtype conformant.
- 17/3 *{AI05-0239-1}* Two profiles are *subtype conformant* if they are mode conformant, corresponding subtypes of the profile statically match, and the associated calling conventions are the same. The profile of a generic formal subprogram is not subtype conformant with any other profile.
- 17.a **Ramification:**
- 18/3 *{AI05-0134-1}* *{AI05-0262-1}* Two profiles are *fully conformant* if they are subtype conformant, if they have access-to-subprogram results whose designated profiles are fully conformant, and for corresponding parameters:
- 18.1/3 • *{AI05-0262-1}* they have the same names; and
- 18.2/3 • *{AI05-0046-1}* both or neither have `null_exclusions`; and
- 18.3/3 • neither have `default_expressions`, or they both have `default_expressions` that are fully conformant with one another; and
- 18.4/3 • *{AI05-0134-1}* for access-to-subprogram parameters, the designated profiles are fully conformant.
- 18.a **Ramification:** Full conformance requires subtype conformance, which requires the same calling conventions. However, the calling convention of the declaration and body of a subprogram or entry are always the same by definition.
- 18.b/3 **Reason:** *{AI05-0046-1}* The part about `null_exclusions` is necessary to prevent controlling parameters from having different exclusions, as such a parameter is defined to exclude null whether or not an exclusion is given.
- 18.c/3 *{AI05-0134-1}* The parts about access-to-subprogram parameters and results is necessary to prevent such types from having different `default_expressions` in the specification and body of a subprogram. If that was allowed, it would be undefined which `default_expression` was used in a call of an access-to-subprogram parameter.
- 19 Two expressions are *fully conformant* if, [after replacing each use of an operator with the equivalent `function_call`:]
- 20 • each constituent construct of one corresponds to an instance of the same syntactic category in the other, except that an expanded name may correspond to a `direct_name` (or `character_literal`) or to a different expanded name in the other; and
- 21 • each `direct_name`, `character_literal`, and `selector_name` that is not part of the prefix of an expanded name in one denotes the same declaration as the corresponding `direct_name`, `character_literal`, or `selector_name` in the other; and
- 21.a **Ramification:** Note that it doesn't say “respectively” because a `direct_name` can correspond to a `selector_name`, and vice-versa, by the previous bullet. This rule allows the prefix of an expanded name to be removed, or replaced with a different prefix that denotes a renaming of the same entity. However, it does not allow a `direct_name` or `selector_name` to be replaced with one denoting a distinct renaming (except for `direct_names` and `selector_names` in prefixes of expanded names). Note that calls using operator notation are equivalent to calls using prefix notation.
- 21.b Given the following declarations:
- 21.c
- ```
package A is
 function F(X : Integer := 1) return Boolean;
end A;
```
- 21.c.1/3
- ```
{AI05-0005-1} with A;
package B is
  package A_View renames A;
  function F_View(X : Integer := 9999) return Boolean renames A.F;
end B;
```
- 21.d
- ```
with A, B; use A, B;
procedure Main is ...
```
- 21.e Within Main, the expressions “F”, “A.F”, “B.A\_View.F”, and “A\_View.F” are all fully conformant with one another. However, “F” and “F\_View” are not fully conformant. If they were, it would be bad news, since the two denoted views have different `default_expressions`.

- {8652/0018} {AI95-00175-01} {AI05-0092-1} each `attribute_designator` in one is the same as the corresponding `attribute_designator` in the other; and 21.1/3
  - each primary that is a literal in one has the same value as the corresponding literal in the other. 22
    - Ramification:** The literals may be written differently. 22.a
    - Ramification:** Note that the above definition makes full conformance a transitive relation. 22.b
- Two `known_discriminant_parts` are *fully conformant* if they have the same number of discriminants, and discriminants in the same positions have the same names, statically matching subtypes, and `default_expressions` that are fully conformant with one another. 23
- Two `discrete_subtype_definitions` are *fully conformant* if they are both `subtype_indications` or are both ranges, the `subtype_marks` (if any) denote the same subtype, and the corresponding `simple_expressions` of the ranges (if any) fully conform. 24
- Ramification:** In the `subtype_indication` case, any ranges have to *be* corresponding; that is, two `subtype_indications` cannot conform unless both or neither has a range. 24.a
  - Discussion:** This definition is used in 9.5.2, “Entries and Accept Statements” for the conformance required between the `discrete_subtype_definitions` of an `entry_declaration` for a family of entries and the corresponding `entry_index_specification` of the `entry_body`. 24.b
- {AI95-00345-01} {AI95-00397-01} The *prefixed view profile* of a subprogram is the profile obtained by omitting the first parameter of that subprogram. There is no prefixed view profile for a parameterless subprogram. For the purposes of defining subtype and mode conformance, the convention of a prefixed view profile is considered to match that of either an entry or a protected operation. 24.1/2
- Discussion:** This definition is used to define how primitive subprograms of interfaces match operations in task and protected type definitions (see 9.1 and 9.4). 24.c/2
  - Reason:** The weird rule about conventions is pretty much required for synchronized interfaces to make any sense. There will be wrappers all over the place for interfaces anyway. Of course, this doesn't imply that entries have the same convention as protected operations. 24.d/2
- Implementation Permissions*
- An implementation may declare an operator declared in a language-defined library unit to be intrinsic. 25
- Extensions to Ada 83*
- The rules for full conformance are relaxed — they are now based on the structure of constructs, rather than the sequence of lexical elements. This implies, for example, that "(X, Y: T)" conforms fully with "(X: T; Y: T)", and "(X: T)" conforms fully with "(X: in T)". 25.a
- Wording Changes from Ada 95*
- {8652/0011} {AI95-00117-01} **Corrigendum:** Clarified that the default convention is Ada. Also clarified that the convention of a primitive operation of a tagged type is the same as that of the type. 25.b/2
  - {8652/0018} {AI95-00175-01} **Corrigendum:** Added wording to ensure that two attributes conform only if they have the same `attribute_designator`. 25.c/2
  - {AI95-00252-01} {AI95-00254-01} {AI95-00407-01} Defined the calling convention for anonymous access-to-subprogram types and for prefixed views of subprograms (see 4.1.3). 25.d/2
  - {AI95-00318-02} Defined the conformance of access result types (see 6.1). 25.e/2
  - {AI95-00345-01} {AI95-00397-01} Defined the prefixed view profile of subprograms for later use. 25.f/2
  - {AI95-00409-01} Defined the conformance of anonymous access-to-subprogram parameters. 25.g/2
- Incompatibilities With Ada 2005*
- {AI05-0046-1} **Correction:** Now require `null_exclusions` to match for full conformance. While this is technically incompatible with Ada 2005 as defined by Amendment 1, it is a new Ada 2005 feature and it is unlikely that users have been intentionally taking advantage of the ability to write mismatching exclusions. In any case, it is easy to fix: add a `null_exclusion` where needed for conformance. 25.h/3

- 25.i/3 {AI05-0134-1} **Correction:** Now require full conformance of anonymous access-to-subprogram parameters and results for full conformance. This is necessary so that there is no confusion about the default expression that is used for a call. While this is technically incompatible with Ada 2005 as defined by Amendment 1, it is a new Ada 2005 feature and it is unlikely that users have been intentionally taking advantage and writing different default expressions. In any case, it is easy to fix: change any default expressions that don't conform so that they do conform.
- 25.j/3 {AI05-0207-1} **Correction:** Now include the presence or absence of **constant** in access parameters to be considered when checking mode conformance. This is necessary to prevent modification of constants. While this is technically incompatible with Ada 2005 as defined by Amendment 1, it is a new Ada 2005 feature and it is unlikely that users have been intentionally taking advantage and writing mismatching access types.
- Wording Changes from Ada 2005*
- 25.k/3 {AI05-0142-4} Explicitly aliased parameters are included as part of mode conformance (since it affects the parameter passing mechanism).

## 6.3.2 Inline Expansion of Subprograms

1 [Subprograms may be expanded in line at the call site.]

*Paragraphs 2 through 4 were moved to Annex J, “Obsolescent Features”.*

### *Static Semantics*

- 5/3 {AI05-0229-1} For a callable entity or a generic subprogram, the following language-defined representation aspect may be specified:
- 5.1/3 **Inline** The type of aspect Inline is Boolean. When aspect Inline is True for a callable entity, inline expansion is desired for all calls to that entity. When aspect Inline is True for a generic subprogram, inline expansion is desired for all calls to all instances of that generic subprogram.
- 5.2/3 If directly specified, the **aspect\_definition** shall be a static expression. [This aspect is never inherited;] if not directly specified, the aspect is False.
- 5.a/3 **Aspect Description for Inline:** For efficiency, Inline calls are requested for a subprogram.
- 5.b/3 *This paragraph was deleted. {AI05-0229-1}*
- 5.c/3 *This paragraph was deleted.*
- 5.d/3 *This paragraph was deleted.*
- 5.e/3 **Ramification:** {AI05-0229-1} The meaning of a subprogram can be changed by inline expansion as requested by aspect Inline only in the presence of failing checks (see 11.6).

### *Implementation Permissions*

- 6/3 {AI05-0229-1} For each call, an implementation is free to follow or to ignore the recommendation determined by the Inline aspect.
- 6.a **Ramification:** Note, in particular, that the recommendation cannot always be followed for a recursive call, and is often infeasible for entries. Note also that the implementation can inline calls even when no such desire was expressed via the Inline aspect, so long as the semantics of the program remains unchanged.

### *Incompatibilities With Ada 83*

- 7.a/3 *This paragraph was deleted. {AI95-00309-01} {AI05-0229-1}*

### *Extensions to Ada 83*

- 7.b/3 *This paragraph was deleted. {AI05-0229-1}*

### *Extensions to Ada 95*

- 7.c/3 *This paragraph was deleted. {AI95-00309-01} {AI05-0229-1}*

{AI05-0229-1} Aspect Inline is new; pragma Inline is now obsolescent.

7.d/3

## 6.4 Subprogram Calls

A *subprogram call* is either a `procedure_call_statement` or a `function_call`; [it invokes the execution of the `subprogram_body`. The call specifies the association of the actual parameters, if any, with formal parameters of the subprogram.]

1

### Syntax

`procedure_call_statement ::=`

2

*procedure\_name*;  
| *procedure\_prefix* `actual_parameter_part`;

`function_call ::=`

3

*function\_name*  
| *function\_prefix* `actual_parameter_part`

**To be honest:** {AI05-0005-1} For the purpose of non-syntax rules, infix operator calls are considered `function_calls`.  
See 6.6.

3.a/3

`actual_parameter_part ::=`

4

(`parameter_association` {, `parameter_association`})

`parameter_association ::=`

5

[*formal\_parameter\_selector\_name* =>] `explicit_actual_parameter`

`explicit_actual_parameter ::= expression` | *variable\_name*

6

A `parameter_association` is *named* or *positional* according to whether or not the *formal\_*-

7

*parameter\_selector\_name* is specified. Any positional associations shall precede any named associations. Named associations are not allowed if the `prefix` in a subprogram call is an `attribute_`-reference.

**Ramification:** This means that the formal parameter names used in describing predefined attributes are to aid presentation of their semantics, but are not intended for use in actual calls.

7.a

### Name Resolution Rules

{AI95-00310-01} The name or prefix given in a `procedure_call_statement` shall resolve to denote a callable entity that is a procedure, or an entry renamed as (viewed as) a procedure. The name or prefix given in a `function_call` shall resolve to denote a callable entity that is a function. The name or prefix shall not resolve to denote an abstract subprogram unless it is also a dispatching subprogram. [When there is an `actual_parameter_part`, the prefix can be an `implicit_dereference` of an access-to-subprogram value.]

8/2

**Discussion:** {AI95-00310-01} This rule is talking about dispatching operations (which is a static concept) and not about dispatching calls (which is a dynamic concept).

8.a.1/2

**Ramification:** The function can be an operator, enumeration literal, attribute that is a function, etc.

8.a

A subprogram call shall contain at most one association for each formal parameter. Each formal parameter without an association shall have a `default_expression` (in the profile of the view denoted by the name or prefix). [This rule is an overloading rule (see 8.6).]

9

**Proof:** {AI05-0240-1} All Name Resolution Rules are overloading rules, see 8.6.

9.a/3

### Dynamic Semantics

{AI95-00345-01} For the execution of a subprogram call, the name or prefix of the call is evaluated, and each `parameter_association` is evaluated (see 6.4.1). If a `default_expression` is used, an implicit

10/2

`parameter_association` is assumed for this rule. These evaluations are done in an arbitrary order. The `subprogram_body` is then executed, or a call on an entry or protected subprogram is performed (see 3.9.2). Finally, if the subprogram completes normally, then after it is left, any necessary assigning back of formal to actual parameters occurs (see 6.4.1).

- 10.a        **Discussion:** The implicit association for a default is only for this run-time rule. At compile time, the visibility rules are applied to the default at the place where it occurs, not at the place of a call.
- 10.b        **To be honest:** If the subprogram is inherited, see 3.4, “Derived Types and Classes”.
- 10.c        If the subprogram is protected, see 9.5.1, “Protected Subprograms and Protected Actions”.
- 10.d        If the subprogram is really a renaming of an entry, see 9.5.3, “Entry Calls”.
- 10.d.1/2    *{AI95-00345-01}* If the subprogram is implemented by an entry or protected subprogram, it will be treated as a dispatching call to the corresponding entry (see 9.5.3, “Entry Calls”) or protected subprogram (see 9.5.1, “Protected Subprograms and Protected Actions”).
- 10.e/2     *{AI95-00348-01}* Normally, the `subprogram_body` that is executed by the above rule is the one for the subprogram being called. For an enumeration literal, implicitly declared (but noninherited) subprogram, null procedure, or an attribute that is a subprogram, an implicit body is assumed. For a dispatching call, 3.9.2, “Dispatching Operations of Tagged Types” defines which `subprogram_body` is executed.
- 10.1/2    *{AI95-00407-01}* If the name or prefix of a subprogram call denotes a prefixed view (see 4.1.3), the subprogram call is equivalent to a call on the underlying subprogram, with the first actual parameter being provided by the prefix of the prefixed view (or the Access attribute of this prefix if the first formal parameter is an access parameter), and the remaining actual parameters given by the `actual_parameter_part`, if any.
- 11/2      *{AI95-00318-02}* The exception `Program_Error` is raised at the point of a `function_call` if the function completes normally without executing a return statement.
- 11.a        **Discussion:** We are committing to raising the exception at the point of call, for uniformity — see AI83-00152. This happens after the function is left, of course.
- 11.b        Note that there is no name for suppressing this check, since the check imposes no time overhead and minimal space overhead (since it can usually be statically eliminated as dead code).
- 12/2      *{AI95-00231-01}* A `function_call` denotes a constant, as defined in 6.5; the nominal subtype of the constant is given by the nominal subtype of the function result.

#### *Examples*

##### 13 *Examples of procedure calls:*

```

14 Traverse_Tree; -- see 6.1
 Print_Header(128, Title, True); -- see 6.1
15 Switch(From => X, To => Next); -- see 6.1
 Print_Header(128, Header => Title, Center => True); -- see 6.1
 Print_Header(Header => Title, Center => True, Pages => 128); -- see 6.1

```

##### 16 *Examples of function calls:*

```

17 Dot_Product(U, V) -- see 6.1 and 6.3
 Clock -- see 9.6
 F.all -- presuming F is of an access-to-subprogram type — see 3.10

```

##### 18 *Examples of procedures with default expressions:*

```

19 procedure Activate(Process : in Process_Name;
 After : in Process_Name := No_Process;
 Wait : in Duration := 0.0;
 Prior : in Boolean := False);
20/3 {AI05-0299-1} procedure Pair(Left, Right : in Person_Name := new Person(M)); --
 see 3.10.1

```

|                                                                                                                                                                                                                                             |      |
|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|------|
| <i>Examples of their calls:</i>                                                                                                                                                                                                             |      |
| Activate(X);                                                                                                                                                                                                                                | 21   |
| Activate(X, After => Y);                                                                                                                                                                                                                    | 22   |
| Activate(X, Wait => 60.0, Prior => True);                                                                                                                                                                                                   |      |
| Activate(X, Y, 10.0, False);                                                                                                                                                                                                                |      |
| {AI05-0299-1} Pair;                                                                                                                                                                                                                         | 23/3 |
| Pair(Left => new Person(F), Right => new Person(M));                                                                                                                                                                                        |      |
| NOTES                                                                                                                                                                                                                                       |      |
| 7 If a default_expression is used for two or more parameters in a multiple parameter_specification, the default_expression is evaluated once for each omitted parameter. Hence in the above examples, the two calls of Pair are equivalent. | 24   |

*Examples*

|                                                         |    |
|---------------------------------------------------------|----|
| <i>Examples of overloaded subprograms:</i>              |    |
| <b>procedure</b> Put(X : in Integer);                   | 25 |
| <b>procedure</b> Put(X : in String);                    | 26 |
| <b>procedure</b> Set(Tint : in Color);                  | 27 |
| <b>procedure</b> Set(Signal : in Light);                |    |
| <i>Examples of their calls:</i>                         |    |
| Put(28);                                                | 28 |
| Put("no possible ambiguity here");                      | 29 |
| Set(Tint => Red);                                       | 30 |
| Set(Signal => Red);                                     |    |
| Set(Color'(Red));                                       |    |
| -- Set(Red) would be ambiguous since Red may            | 31 |
| -- denote a value either of type Color or of type Light |    |

*Wording Changes from Ada 83*

|                                                                                                                                                                                       |      |
|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|------|
| We have gotten rid of parameters “of the form of a type conversion” (see RM83-6.4.1(3)). The new view semantics of type_conversions allows us to use normal type_conversions instead. | 31.a |
| We have moved wording about run-time semantics of parameter associations to 6.4.1.                                                                                                    | 31.b |
| We have moved wording about raising Program_Error for a function that falls off the end to here from RM83-6.5.                                                                        | 31.c |

*Extensions to Ada 95*

|                                                                                                                                                                                                                                                                                            |        |
|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------|
| {AI95-00310-01} Nondispatching abstract operations are no longer considered when resolving a subprogram call. That makes it possible to use <b>abstract</b> to “undefine” a predefined operation for an untagged type. That’s especially helpful when defining custom arithmetic packages. | 31.d/2 |
|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------|

*Wording Changes from Ada 95*

|                                                                                                                                                                                           |        |
|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------|
| {AI95-00231-01} Changed the definition of the nominal subtype of a function_call to use the nominal subtype wording of 6.1, to take into account null_exclusions and access result types. | 31.e/2 |
| {AI95-00345-01} Added wording to clarify that the meaning of a call on a subprogram “implemented by” an entry or protected operation is defined by 3.9.2.                                 | 31.f/2 |
| {AI95-00407-01} Defined the meaning of a call on a prefixed view of a subprogram (see 4.1.3).                                                                                             | 31.g/2 |

## 6.4.1 Parameter Associations

[ A parameter association defines the association between an actual parameter and a formal parameter.] 1

*Language Design Principles*

|                                                                                                                                                                                                                                                     |       |
|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------|
| The parameter passing rules for <b>out</b> parameters are designed to ensure that the parts of a type that have implicit initial values (see 3.3.1) don’t become “de-initialized” by being passed as an <b>out</b> parameter.                       | 1.a   |
| {AI05-0142-4} For explicitly aliased parameters of functions, we will ensure at the call site that a part of the parameter can be returned as part of the function result without creating a dangling pointer. We do this with accessibility checks | 1.b/3 |

at the call site that all actual objects of explicitly aliased parameters live at least as long as the function result; then we can allow them to be returned as access discriminants or anonymous access results, as those have the master of the function result.

#### Name Resolution Rules

2/3 *{AI05-0118-1}* The *formal\_parameter\_selector\_name* of a named *parameter\_association* shall resolve to denote a *parameter\_specification* of the view being called; this is the formal parameter of the association. The formal parameter for a positional *parameter\_association* is the parameter with the corresponding position in the formal part of the view being called.

2.a/3 **To be honest:** *{AI05-0118-1}* For positional parameters, the “corresponding position” is calculated after any transformation of prefixed views.

3 The *actual parameter* is either the *explicit\_actual\_parameter* given in a *parameter\_association* for a given formal parameter, or the corresponding *default\_expression* if no *parameter\_association* is given for the formal parameter. The expected type for an actual parameter is the type of the corresponding formal parameter.

3.a **To be honest:** The corresponding *default\_expression* is the one of the corresponding formal parameter in the profile of the view denoted by the name or prefix of the call.

4 If the mode is **in**, the actual is interpreted as an **expression**; otherwise, the actual is interpreted only as a **name**, if possible.

4.a **Ramification:** This formally resolves the ambiguity present in the syntax rule for *explicit\_actual\_parameter*. Note that we don't actually require that the actual be a name if the mode is not **in**; we do that below.

#### Legality Rules

5 If the mode is **in out** or **out**, the actual shall be a **name** that denotes a variable.

5.a **Discussion:** We no longer need “or a *type\_conversion* whose argument is the name of a variable,” because a *type\_conversion* is now a **name**, and a *type\_conversion* of a variable is a variable.

5.b **Reason:** The requirement that the actual be a (variable) **name** is not an overload resolution rule, since we don't want the difference between **expression** and **name** to be used to resolve overloading. For example:

```
5.c procedure Print(X : in Integer; Y : in Boolean := True);
 procedure Print(Z : in out Integer);
 .
 Print(3); -- Ambiguous!
```

5.d The above call to `Print` is ambiguous even though the call is not compatible with the second `Print` which requires an actual that is a (variable) **name** (“3” is an **expression**, not a **name**). This requirement is a legality rule, so overload resolution fails before it is considered, meaning that the call is ambiguous.

6/3 *{AI05-0102-1}* *{AI05-0142-4}* If the formal parameter is an explicitly aliased parameter, the type of the actual parameter shall be tagged or the actual parameter shall be an aliased view of an object. Further, if the formal parameter subtype *F* is untagged:

- 6.1/3 • the subtype *F* shall statically match the nominal subtype of the actual object; or
- 6.2/3 • the subtype *F* shall be unconstrained, discriminated in its full view, and unconstrained in any partial view.

6.a/3 **Ramification:** Tagged objects (and tagged **aggregates** for **in** parameters) do not need to be aliased. This matches the behavior of unaliased formal parameters of tagged types, which allow 'Access to be taken of the formal parameter regardless of the form of the actual parameter.

6.b/3 **Reason:** We need the subtype check on untagged actual parameters so that the requirements of 'Access are not lost. 'Access makes its checks against the nominal subtype of its prefix, and parameter passing can change that subtype. But we don't want this parameter passing to change the objects that would be allowed as the prefix of 'Access. This is particularly important for arrays, where we don't want to require any additional implementation burden.

{AI05-0142-4} {AI05-0234-1} In a function call, the accessibility level of the actual object for each explicitly aliased parameter shall not be statically deeper than the accessibility level of the master of the call (see 3.10.2). 6.3/3

**Discussion:** Since explicitly aliased parameters are either tagged or required to be objects, there is always an object (possibly anonymous) to talk about. This is discussing the static accessibility level of the actual object; it does not depend on any runtime information (for instance when the actual object is a formal parameter of another subprogram, it does not depend on the actual parameter of that other subprogram). 6.c/3

**Ramification:** This accessibility check (and its dynamic cousin as well) can only fail if the function call is used to directly initialize a built-in-place object with a master different than that enclosing the call. The only place all of those conditions exist is in the initializer of an allocator; in all other cases this check will always pass. 6.d/3

{AI05-0144-2} Two names are *known to denote the same object* if: 6.4/3

- both names statically denote the same stand-alone object or parameter; or 6.5/3
- both names are `selected_components`, their prefixes are known to denote the same object, and their `selector_names` denote the same component; or 6.6/3
- both names are dereferences (implicit or explicit) and the dereferenced names are known to denote the same object; or 6.7/3
- both names are `indexed_components`, their prefixes are known to denote the same object, and each of the pairs of corresponding index values are either both static expressions with the same static value or both names that are known to denote the same object; or 6.8/3
- both names are `slices`, their prefixes are known to denote the same object, and the two slices have statically matching index constraints; or 6.9/3
- one of the two names statically denotes a renaming declaration whose renamed *object\_name* is known to denote the same object as the other, the prefix of any dereference within the renamed *object\_name* is not a variable, and any expression within the renamed *object\_name* contains no references to variables nor calls on nonstatic functions. 6.10/3

**Reason:** This exposes known renamings of slices, indexing, and so on to this definition. In particular, if we have 6.e/3

```
C : Character renames S(1);
```

then C and S(1) are known to denote the same object. 6.f/3

We need the requirement that no variables occur in the prefixes of dereferences and in (index) expressions of the renamed object in order to avoid problems from later changes to those parts of renamed names. Consider: 6.h/3

```
type Ref is access Some_Type;
Ptr : Ref := new Some_Type'(...);
X : Some_Type renames Ptr.all;
begin
 Ptr := new Some_Type'(...);
 P (Func_With_Out_Params (Ptr.all), X);
```

X and `Ptr.all` should not be known to denote the same object, since they denote different allocated objects (and this is not an unreasonable thing to do). 6.j/3

**To be honest:** The exclusion of variables from renamed *object\_names* is not enough to prevent altering the value of the name or expression by another access path. For instance, both `in` parameters passed by reference and access-to-constant values can designate variables. For the intended use of "known to be the same object", this is OK; the modification via another access path is very tricky and it is OK to reject code that would be buggy except for the tricky code. Assuming `Element` is an elementary type, consider the following example: 6.k/3

```
Global : Tagged_Type;
procedure Foo (Param : in Tagged_Type := Global) is
 X : Element renames Some_Global_Array (Param.C);
begin
 Global.C := Global.C + 1;
 Swap (X, Some_Global_Array (Param.C));
```

The rules will flag the call of procedure `Swap` as illegal, since X and `Some_Global_Array (Parameter.C)` are known to denote the same object (even though they will actually represent different objects if `Param = Global`). But this is only incorrect if the parameter actually is `Global` and not some other value; the error could exist for some calls. So this flagging seems harmless. 6.n/3

- 6.o/3 Similar examples can be constructed using stand-alone composite constants with controlled or immutably limited components, and (as previously noted) with dereferences of access-to-constant values. Even when these examples flag a call incorrectly, that call depends on very tricky code (modifying the value of a constant); the code is likely to confuse future maintainers as well and thus we do not mind rejecting it.
- 6.p/3 **Discussion:** Whether or not names or prefixes are known to denote the same object is determined statically. If the name contains some dynamic portion other than a dereference, `indexed_component`, or `slice`, it is not "known to denote the same object".
- 6.q/3 These rules make no attempt to handle slices of objects that are known to be the same when the slices have dynamic bounds (other than the trivial case of bounds being defined by the same subtype), even when the bounds could be proven to be the same, as it is just too complex to get right and these rules are intended to be conservative.
- 6.r/3 **Ramification:** "Known to denote the same object" is intended to be an equivalence relationship, that is, it is reflexive, symmetric, and transitive. We believe this follows from the rules. For instance, given the following declarations:
- 6.s/3
- ```
S : String(1..10);
ONE : constant Natural := 1;
R : Character renames S(1);
```
- 6.t/3 the names `R` and `S(1)` are known to denote the same object by the sixth bullet, and `S(1)` and `S(ONE)` are known to denote the same object by the fourth bullet, so using the sixth bullet on `R` and `S(ONE)`, we simply have to test `S(1)` vs. `S(ONE)`, which we already know denote the same object.
- 6.11/3 {AI05-0144-2} Two names are *known to refer to the same object* if
- 6.12/3
- The two names are known to denote the same object; or
- 6.13/3
- One of the names is a `selected_component`, `indexed_component`, or `slice` and its prefix is known to refer to the same object as the other name; or
- 6.14/3
- One of the two names statically denotes a renaming declaration whose renamed *object_name* is known to refer to the same object as the other name.
- 6.u/3 **Reason:** This ensures that names `Prefix.Comp` and `Prefix` are known to refer to the same object for the purposes of the rules below. This intentionally does not include dereferences; we only want to worry about accesses to the same object, and a dereference changes the object in question. (There is nothing shared between an access value and the object it designates.)
- 6.15/3 {AI05-0144-2} If a call *C* has two or more parameters of mode **in out** or **out** that are of an elementary type, then the call is legal only if:
- 6.16/3
- For each name *N* that is passed as a parameter of mode **in out** or **out** to the call *C*, there is no other name among the other parameters of mode **in out** or **out** to *C* that is known to denote the same object.
- 6.v/3 **To be honest:** This means *visibly* an elementary type; it does not include partial views of elementary types (partial views are always composite). That's necessary to avoid having Legality Rules depend on the contents of the private part.
- 6.17/3 {AI05-0144-2} If a construct *C* has two or more direct constituents that are names or expressions whose evaluation may occur in an arbitrary order, at least one of which contains a function call with an **in out** or **out** parameter, then the construct is legal only if:
- 6.w/3 **Ramification:** All of the places where the language allows an arbitrary order can be found by looking in the index under "arbitrary order, allowed". Note that this listing includes places that don't involve names or expressions (such as checks or finalization).
- 6.18/3
- For each name *N* that is passed as a parameter of mode **in out** or **out** to some inner function call *C2* (not including the construct *C* itself), there is no other name anywhere within a direct constituent of the construct *C* other than the one containing *C2*, that is known to refer to the same object.
- 6.x/3 **Ramification:** This requirement cannot fail for a procedure or entry call alone; there must be at least one function with an **in out** or **out** parameter called as part of a parameter expression of the call in order for it to fail.
- 6.y/3 **Reason:** These rules prevent obvious cases of dependence on the order of evaluation of names or expressions. Such dependence is usually a bug, and in any case, is not portable to another implementation (or even another optimization setting).

- In the case that the top-level construct *C* is a call, these rules do not require checks for most **in out** parameters, as the rules about evaluation of calls prevent problems. Similarly, we do not need checks for short circuit operations or other operations with a defined order of evaluation. The rules about arbitrary order (see 1.1.4) allow evaluating parameters and writing parameters back in an arbitrary order, but not interleaving of evaluating parameters of one call with writing parameters back from another — that would not correspond to any allowed sequential order. 6.z/3
- {AI05-0144-2} For the purposes of checking this rule: 6.19/3
- For an array aggregate, an expression associated with a discrete_choice_list that has two or more discrete choices, or that has a nonstatic range, is considered as two or more separate occurrences of the expression; 6.20/3
 - For a record aggregate: 6.21/3
 - The expression of a record_component_association is considered to occur once for each associated component; and 6.22/3
 - The default_expression for each record_component_association with \diamond for which the associated component has a default_expression is considered part of the aggregate; 6.23/3
 - For a call, any default_expression evaluated as part of the call is considered part of the call. 6.24/3

Ramification: We do not check expressions that are evaluated only because of a component initialized by default in an aggregate (via \diamond). 6.aa/3

Dynamic Semantics

- For the evaluation of a parameter_association: 7
- The actual parameter is first evaluated. 8
 - For an access parameter, the access_definition is elaborated, which creates the anonymous access type. 9
 - For a parameter [(of any mode)] that is passed by reference (see 6.2), a view conversion of the actual parameter to the nominal subtype of the formal parameter is evaluated, and the formal parameter denotes that conversion. 10

Discussion: We are always allowing sliding, even for [in] out by-reference parameters. 10.a
 - For an **in** or **in out** parameter that is passed by copy (see 6.2), the formal parameter object is created, and the value of the actual parameter is converted to the nominal subtype of the formal parameter and assigned to the formal. 11

Ramification: The conversion mentioned here is a value conversion. 11.a
 - For an **out** parameter that is passed by copy, the formal parameter object is created, and: 12
 - {AI05-0153-3} {AI05-0196-1} For an access type, the formal parameter is initialized from the value of the actual, without checking that the value satisfies any constraint, any predicate, or any exclusion of the null value; 13/3

Reason: This preserves the Language Design Principle that an object of an access type is always initialized with a “reasonable” value. 13.a
 - {AI05-0153-3} {AI05-0228-1} For a scalar type that has the Default_Value aspect specified, the formal parameter is initialized from the value of the actual, without checking that the value satisfies any constraint or any predicate; 13.1/3

Reason: This preserves the Language Design Principle that all objects of a type with an implicit initial value are initialized. This is important so that a programmer can guarantee that all objects of a scalar type have a valid value with a carefully chosen Default_Value. 13.b/3

Implementation Note: This rule means that **out** parameters of a subtype *T* with a specified Default_Value need to be large enough to support any possible value of the base type of *T*. In contrast, a type that does not have a Default_Value only need support the size of the subtype (since no values are passed in). 13.c/3
 - For a composite type with discriminants or that has implicit initial values for any subcomponents (see 3.3.1), the behavior is as for an **in out** parameter passed by copy. 14

- 14.a **Reason:** This ensures that no part of an object of such a type can become “de-initialized” by being part of an **out** parameter.
- 14.b **Ramification:** This includes an array type whose component type is an access type, and a record type with a component that has a `default_expression`, among other things.
- 15
- For any other type, the formal parameter is uninitialized. If composite, a view conversion of the actual parameter to the nominal subtype of the formal is evaluated [(which might raise `Constraint_Error`)], and the actual subtype of the formal is that of the view conversion. If elementary, the actual subtype of the formal is given by its nominal subtype.
- 15.a/3 **Ramification:** {*AI05-0228-1*} This case covers scalar types that do not have `Default_Value` specified, and composite types whose subcomponent's subtypes do not have any implicit initial values. The view conversion for composite types ensures that if the lengths don't match between an actual and a formal array parameter, the `Constraint_Error` is raised before the call, rather than after.
- 15.1/3
- {*AI05-0142-4*} {*AI05-0234-1*} In a function call, for each explicitly aliased parameter, a check is made that the accessibility level of the master of the actual object is not deeper than that of the master of the call (see 3.10.2).
- 15.a.1/3 **Ramification:** If the actual object to a call *C* is a formal parameter of some function call *F*, no dynamic check against the master of the actual parameter of *F* is necessary. Any case which could fail the dynamic check is already statically illegal (either at the call site of *F*, or at the call site *C*). This is important, as it would require nasty distributed overhead to accurately know the dynamic accessibility of a formal parameter (all tagged and explicitly aliased parameters would have to carry accessibility levels).
- 16 A formal parameter of mode **in out** or **out** with discriminants is constrained if either its nominal subtype or the actual parameter is constrained.
- 17 After normal completion and leaving of a subprogram, for each **in out** or **out** parameter that is passed by copy, the value of the formal parameter is converted to the subtype of the variable given as the actual parameter and assigned to it. These conversions and assignments occur in an arbitrary order.
- 17.a **Ramification:** The conversions mentioned above during parameter passing might raise `Constraint_Error` — (see 4.6).
- 17.b **Ramification:** If any conversion or assignment as part of parameter passing propagates an exception, the exception is raised at the place of the subprogram call; that is, it cannot be handled inside the `subprogram_body`.
- 17.c **Proof:** Since these checks happen before or after executing the `subprogram_body`, the execution of the `subprogram_body` does not dynamically enclose them, so it can't handle the exceptions.
- 17.d **Discussion:** The variable we're talking about is the one denoted by the *variable_name* given as the `explicit_actual_parameter`. If this *variable_name* is a `type_conversion`, then the rules in 4.6 for assigning to a view conversion apply. That is, if X is of subtype S1, and the actual is S2(X), the above-mentioned conversion will convert to S2, and the one mentioned in 4.6 will convert to S1.

Erroneous Execution

- 18/3 {*AI05-0008-1*} If the nominal subtype of a formal parameter with discriminants is constrained or indefinite, and the parameter is passed by reference, then the execution of the call is erroneous if the value of any discriminant of the actual is changed while the formal parameter exists (that is, before leaving the corresponding callable construct).

Extensions to Ada 83

- 18.a In Ada 95, a program can rely on the fact that passing an object as an **out** parameter does not “de-initialize” any parts of the object whose subtypes have implicit initial values. (This generalizes the RM83 rule that required copy-in for parts that were discriminants or of an access type.)

Wording Changes from Ada 83

- 18.b/3 {*AI05-0299-1*} We have eliminated the subclause on Default Parameters, as it is subsumed by earlier subclauses.

Inconsistencies With Ada 2005

- 18.c/3 {*AI05-0196-1*} **Correction:** Clarified that **out** parameters of an access type are not checked for null exclusions when they are passed in (which is similar to the behavior for constraints). This was unspecified in Ada 2005, so a program

which depends on the behavior of an implementation which does check the exclusion may malfunction. But a program depending on an exception being raised is unlikely.

Incompatibilities With Ada 2005

{AI05-0144-2} Additional rules have been added to make illegal passing the same elementary object to more than one **in out** or **out** parameters of the same call. In this case, the result in the object could depend on the compiler version, optimization settings, and potentially the phase of the moon, so this check will mostly reject programs that are nonportable and could fail with any change. Even when the result is expected to be the same in both parameters, the code is unnecessarily tricky. Programs which fail this new check should be rare and are easily fixed by adding a temporary object. 18.d/3

Wording Changes from Ada 2005

{AI05-0008-1} **Correction:** A missing rule was added to cover cases that were missed in Ada 95 and Ada 2005; specifically, that an **in** parameter passed by reference might have its discriminants changed via another path. Such cases are erroneous as requiring compilers to detect such errors would be expensive, and requiring such cases to work would be a major change of the user model (**in** parameters with discriminants could no longer be assumed constant). This is not an inconsistency, as compilers are not required to change any current behavior. 18.e/3

{AI05-0102-1} **Correction:** Moved implicit conversion Legality Rule to 8.6. 18.f/3

{AI05-0118-1} **Correction:** Added a definition for positional parameters, as this is missing from Ada 95 and later. 18.g/3

{AI05-0142-4} Rules have been added defining the legality and dynamic checks needed for explicitly aliased parameters (see 6.1). 18.h/3

{AI05-0144-2} Additional rules have been added such that passing an object to an **in out** or **out** parameter of a function is illegal if it is used elsewhere in a construct which allows evaluation in an arbitrary order. Such calls are not portable (since the results may depend on the evaluation order), and the results could even vary because of optimization settings and the like. Thus they've been banned. 18.i/3

6.5 Return Statements

{AI95-00318-02} A `simple_return_statement` or `extended_return_statement` (collectively called a *return statement*) is used to complete the execution of the innermost enclosing `subprogram_body`, `entry_body`, or `accept_statement`. 1/2

Syntax

{AI95-00318-02} `simple_return_statement ::= return [expression];` 2/2

{AI05-0277-1} `extended_return_object_declaration ::=`
`defining_identifier : [aliased][constant] return_subtype_indication [:= expression]` 2.1/3

{AI95-00318-02} {AI05-0015-1} {AI05-0053-1} {AI05-0277-1} {AI05-0299-1} 2.2/3
`extended_return_statement ::=`
`return extended_return_object_declaration [do`
`handled_sequence_of_statements`
`end return];`

{AI95-00318-02} `return_subtype_indication ::= subtype_indication | access_definition` 2.3/2

Name Resolution Rules

{AI95-00318-02} The *result subtype* of a function is the subtype denoted by the `subtype_mark`, or defined by the `access_definition`, after the reserved word **return** in the profile of the function. The expected type for the `expression`, if any, of a `simple_return_statement` is the result type of the corresponding function. The expected type for the `expression` of an `extended_return_statement` is that of the `return_subtype_indication`. 3/2

To be honest: The same applies to generic functions. 3.a

- 4/2 {AI95-00318-02} A return statement shall be within a callable construct, and it *applies to* the innermost callable construct or `extended_return_statement` that contains it. A return statement shall not be within a body that is within the construct to which the return statement applies.
- 5/3 {AI95-00318-02} {AI05-0015-1} A function body shall contain at least one return statement that applies to the function body, unless the function contains `code_statements`. A `simple_return_statement` shall include an `expression` if and only if it applies to a function body. An `extended_return_statement` shall apply to a function body. An `extended_return_statement` with the reserved word **constant** shall include an `expression`.
- 5.a/2 **Reason:** {AI95-00318-02} The requirement that a function body has to have at least one return statement is a “helpful” restriction. There has been some interest in lifting this restriction, or allowing a `raise` statement to substitute for the return statement. However, there was enough interest in leaving it as is that we decided not to change it.
- 5.b/2 **Ramification:** {AI95-00318-02} A return statement can apply to an `extended_return_statement`, so a `simple_return_statement` without an `expression` can be given in one. However, neither `simple_return_statement` with an `expression` nor an `extended_return_statement` can be given inside an `extended_return_statement`, as they must apply (directly) to a function body.
- 5.1/2 {AI95-00318-02} For an `extended_return_statement` that applies to a function body:
- 5.2/3 • {AI95-00318-02} {AI05-0032-1} {AI05-0103-1} If the result subtype of the function is defined by a `subtype_mark`, the `return_subtype_indication` shall be a `subtype_indication`. The type of the `subtype_indication` shall be covered by the result type of the function. The subtype defined by the `subtype_indication` shall be statically compatible with the result subtype of the function; if the result type of the function is elementary, the two subtypes shall statically match. If the result subtype of the function is indefinite, then the subtype defined by the `subtype_indication` shall be a definite subtype, or there shall be an `expression`.
- 5.3/2 • {AI95-00318-02} If the result subtype of the function is defined by an `access_definition`, the `return_subtype_indication` shall be an `access_definition`. The subtype defined by the `access_definition` shall statically match the result subtype of the function. The accessibility level of this anonymous access subtype is that of the result subtype.
- 5.4/3 • {AI05-0032-1} If the result subtype of the function is class-wide, the accessibility level of the type of the subtype defined by the `return_subtype_indication` shall not be statically deeper than that of the master that elaborated the function body.
- 5.b.1/3 **Reason:** In this case, the `return_subtype_indication` could be a specific type initialized by default; in that case there is no `expression` to check.
- 5.5/3 {AI95-00318-02} {AI05-0032-1} For any return statement that applies to a function body:
- 5.6/3 • {AI95-00318-02} {AI05-0188-1} [If the result subtype of the function is limited, then the `expression` of the return statement (if any) shall meet the restrictions described in 7.5.]
- 5.c/3 *This paragraph was deleted.* {AI05-0188-1}
- 5.7/3 • {AI95-00416-01} {AI05-0032-1} {AI05-0051-1} If the result subtype of the function is class-wide, the accessibility level of the type of the `expression` (if any) of the return statement shall not be statically deeper than that of the master that elaborated the function body.
- 5.d/3 **Discussion:** {AI05-0032-1} {AI05-0051-1} If the result type is class wide, then there must be an `expression` of the return statement unless this is an `extended_return_statement` whose `return_subtype_indication` is a specific type. We have a separate rule to cover that case. Note that if an `extended_return_statement` has an `expression`, then both this rule and the next one must be satisfied.
- 5.8/3 • {AI05-0051-1} If the subtype determined by the `expression` of the `simple_return_statement` or by the `return_subtype_indication` has one or more access discriminants, the accessibility level of the anonymous access type of each access discriminant shall not be statically deeper than that of the master that elaborated the function body.

- Discussion:** We use the type used by the return statement rather than from the function return type since we want to check whenever the return object has access discriminants, even if the function return type doesn't have any (mostly for a class-wide type). 5.d.1/3
- {AI05-0277-1} If the keyword **aliased** is present in an `extended_return_object_declaration`, the type of the extended return object shall be immutably limited. 5.9/3
- Static Semantics*
- {AI95-00318-02} {AI05-0015-1} {AI05-0144-2} Within an `extended_return_statement`, the *return object* is declared with the given `defining_identifier`, with the nominal subtype defined by the `return_subtype_indication`. An `extended_return_statement` with the reserved word **constant** is a full constant declaration that declares the return object to be a constant object. 5.10/3
- Dynamic Semantics*
- {AI95-00318-02} {AI95-00416-01} {AI05-0032-1} For the execution of an `extended_return_statement`, the `subtype_indication` or `access_definition` is elaborated. This creates the nominal subtype of the return object. If there is an `expression`, it is evaluated and converted to the nominal subtype (which might raise `Constraint_Error` — see 4.6); the return object is created and the converted value is assigned to the return object. Otherwise, the return object is created and initialized by default as for a stand-alone object of its nominal subtype (see 3.3.1). If the nominal subtype is indefinite, the return object is constrained by its initial value. A check is made that the value of the return object belongs to the function result subtype. `Constraint_Error` is raised if this check fails. 5.11/3
- Ramification:** If the result type is controlled or has a controlled part, appropriate calls on `Initialize` or `Adjust` are performed prior to executing the `handled_sequence_of_statements`, except when the initial expression is an aggregate (which requires build-in-place with no call on `Adjust`). 5.e/2
- {AI05-0005-1} If the return statement is left without resulting in a return (for example, due to an exception propagated from the `expression` or the `handled_sequence_of_statements`, or a `goto` out of the `handled_sequence_of_statements`), if the return object has been created, it is finalized prior to leaving the return statement. If it has not been created when the return statement is left, it is not created or finalized. 5.f/3
- {AI05-0032-1} Other rules ensure that the check required by this rule cannot fail unless the function has a class-wide result subtype where the associated specific subtype is constrained. In other cases, either the subtypes have to match or the function's subtype is unconstrained and needs no checking. 5.g/3
- {AI95-00318-02} For the execution of a `simple_return_statement`, the `expression` (if any) is first evaluated, converted to the result subtype, and then is assigned to the anonymous *return object*. 6/2
- Ramification:** The conversion might raise `Constraint_Error` — (see 4.6). 6.a
- {AI95-00318-02} {AI95-00416-01} [If the return object has any parts that are tasks, the activation of those tasks does not occur until after the function returns (see 9.2).] 7/2
- Proof:** This is specified by the rules in 9.2. 7.a/2
- Reason:** Only the caller can know when task activations should take place, as it depends on the context of the call. If the function is being used to initialize the component of some larger object, then that entire object must be initialized before any task activations. Even after the outer object is fully initialized, task activations are still postponed until the **begin** at the end of the declarative part if the function is being used to initialize part of a declared object. 7.b/2
- {AI95-00318-02} {AI95-00344-01} {AI05-0024-1} {AI05-0032-1} If the result type of a function is a specific tagged type, the tag of the return object is that of the result type. If the result type is class-wide, the tag of the return object is that of the type of the `subtype_indication` if it is specific, or otherwise that of the value of the `expression`. A check is made that the master of the type identified by the tag of the result includes the elaboration of the master that elaborated the function body. If this check fails, `Program_Error` is raised. 8/3
- Ramification:** {AI95-00318-02} The first sentence is true even if the tag of the `expression` is different, which could happen if the `expression` were a view conversion or a dereference of an access value. Note that for a limited type, because of the restriction to aggregates and function calls (and no conversions), the tag will already match. 8.a/2

- 8.b/2 **Reason:** {AI95-00318-02} The first rule ensures that a function whose result type is a specific tagged type always returns an object whose tag is that of the result type. This is important for dispatching on controlling result, and allows the caller to allocate the appropriate amount of space to hold the value being returned (assuming there are no discriminants).
- 8.c/3 The master check prevents the returned object from outliving its type. Note that this check cannot fail for a specific tagged type, as the tag represents the function's type, which necessarily must be declared outside of the function.
- 8.d/3 We can't use the normal accessibility level “deeper than” check here because we may have “incomparable” levels if the masters belong to two different tasks. This can happen when an accept statement calls a function declared in the enclosing task body, and the function returns an object passed to it from the accept statement, and this object was itself a parameter to the accept statement.
- 8.1/3 {AI05-0073-1} If the result subtype of the function is defined by an `access_definition` designating a specific tagged type *T*, a check is made that the result value is null or the tag of the object designated by the result value identifies *T*. `Constraint_Error` is raised if this check fails.
- 8.e/3 **Reason:** This check is needed so that dispatching on controlling access results works for tag-indeterminate functions. If it was not made, it would be possible for such functions to return an access to a descendant type, meaning the function could return an object with a tag different than the one assumed by the dispatching rules.

Paragraphs 9 through 20 were deleted.

- 21/3 {AI95-00318-02} {AI95-00402-01} {AI95-00416-01} {AI05-0051-1} If any part of the specific type of the return object of a function (or coextension thereof) has one or more access discriminants whose value is not constrained by the result subtype of the function, a check is made that the accessibility level of the anonymous access type of each access discriminant, as determined by the `expression` or the `return_subtype_indication` of the return statement, is not deeper than the level of the master of the call (see 3.10.2). If this check fails, `Program_Error` is raised.
- 21.a/2 *This paragraph was deleted.*
- 21.b/2 **Reason:** The check prevents the returned object (for a nonlimited type) from outliving the object designated by one of its discriminants. The check is made on the values of the discriminants, which may come from the `return_subtype_indication` (if constrained), or the `expression`, but it is never necessary to check both.
- 21.c/3 **Implementation Note:** {AI05-0234-1} The reason for saying “any part of the specific type” is to simplify implementation. In the case of class-wide result objects, this allows the testing of a simple flag in the tagged type descriptor that indicates whether the specific type has any parts with access discriminants. By basing the test on the type of the object rather than the object itself, we avoid concerns about whether subcomponents in variant parts and of arrays (which might be empty) are present.
- 21.d/3 **Discussion:** {AI05-0234-1} For a function with a class-wide result type, the access values that need to be checked are determined by the tag of the return object. In order to implement this accessibility check in the case where the tag of the result is not known statically at the point of the return statement, an implementation may need to somehow associate with the tag of a specific tagged type an indication of whether the type has unconstrained access discriminants (explicit or inherited) or has any subcomponents with such discriminants. If an implementation is already maintaining a statically initialized descriptor of some kind for each specific tagged type, then an additional Boolean could be added to this descriptor.
- 21.e/3 {AI05-0005-1} {AI05-0234-1} Note that the flag should only be queried in the case where the result object might have access discriminants that might have subtypes with “bad” accessibility levels (as determined by the rules of 3.10.2 for determining the accessibility level of the type of an access discriminant in the `expression` or `return_subtype_indication` of a return statement).
- 21.f/3 Thus, in a case like
- 21.g/3

```
type Global is access T'Class;
function F (Ptr : Global) return T'Class is
begin
  return Ptr.all;
end F;
```
- 21.h/3 there is no need for a run-time accessibility check. While an object of T'Class “might have” access discriminants, the accessibility of those potential discriminants cannot be bad. The setting of the bit doesn't matter and there is no need to query it.
- 21.i/3 On the other hand, given

```

function F return T'Class is
  Local : T'Class := ... ;
begin
  return Local;
end F;

```

In this case, a check would typically be required. 21.j/3

The need for including subcomponents in this check is illustrated by the following example: 21.l/3

```

X : aliased Integer;
type Component_Type (Discrim : access Integer := X'Access)
  is limited null record;
type Undiscriminated is record
  Fld : Component_Type;
end record;
function F return Undiscriminated is
  Local : aliased Integer;
begin
  return X : Undiscriminated := (Fld => (Discrim => Local'Access)) do
    Foo;
  end return;
  -- raises Program_Error after calling Foo.
end F;

```

Ramification: {AI05-0234-1} In the case where the tag of the result is not known statically at the point of the return statement and the run-time accessibility check is needed, discriminant values and array bounds play no role in performing this check. That is, array components are assumed to have nonzero length and components declared within variant parts are assumed to be present. Thus, the check may be implemented simply by testing the aforementioned descriptor bit and conditionally raising Program_Error. 21.o/3

{AI95-00318-02} {AI05-0058-1} For the execution of an `extended_return_statement`, the `handled_sequence_of_statements` is executed. Within this `handled_sequence_of_statements`, the execution of a `simple_return_statement` that applies to the `extended_return_statement` causes a transfer of control that completes the `extended_return_statement`. Upon completion of a return statement that applies to a callable construct by the normal completion of a `simple_return_statement` or by reaching the `end return` of an `extended_return_statement`, a transfer of control is performed which completes the execution of the callable construct, and returns to the caller. 22/3

Ramification: {AI05-0058-1} A transfer of control that completes an `extended_return_statement` (such as an exit or goto) does not cause a return to the caller unless it is caused by `simple_return_statement` (that is, triggers the second sentence of this paragraph). The return to the caller occurs for the `simple_return_statement` that applies to an `extended_return_statement` because the last sentence says “the normal completion of a `simple_return_statement`”, which includes the one nested in the `extended_return_statement`. 22.a/3

{AI95-00318-02} In the case of a function, the `function_call` denotes a constant view of the return object. 23/2

Implementation Permissions

{AI95-00416-01} {AI05-0050-1} For a function call used to initialize a composite object with a constrained nominal subtype or used to initialize a return object that is built in place into such an object: 24/3

- {AI05-0050-1} If the result subtype of the function is constrained, and conversion of an object of this subtype to the subtype of the object being initialized would raise Constraint_Error, then Constraint_Error may be raised before calling the function. 24.1/3
- {AI05-0050-1} If the result subtype of the function is unconstrained, and a return statement is executed such that the return object is known to be constrained, and conversion of the return object to the subtype of the object being initialized would raise Constraint_Error, then Constraint_Error may be raised at the point of the call (after abandoning the execution of the function body). 24.2/3

Reason: {AI95-00416-01} {AI05-0050-1} Without such a permission, it would be very difficult to implement “built-in-place” semantics. The intention is that the exception is raised at the same point that it would have been raised without the permission; it should not change handlers if the implementation switches between return-by-copy and built-in-place. This means that the exception is not handleable within the function, because in the return-by-copy case, the constraint check to verify that the result satisfies the constraints of the object being initialized happens after the 24.a/3

function returns. This implies further that upon detecting such a situation, the implementation may need to simulate a goto to a point outside any local exception handlers prior to raising the exception.

- 24.b/3 **Ramification:** {AI95-00416-01} {AI05-0050-1} These permissions do not apply in the case of an extended return object with mutable discriminants. That's necessary because in that case a return object can be created with the “wrong” discriminants and then changed to the “right” discriminants later (but before returning). We don't want this case raising an exception when the canonical semantics will not do so.
- 24.c/3 {AI05-0050-1} It's still possible to write a program that will raise an exception using this permission that would not in the canonical semantics. That could happen if a return statement with the “wrong” discriminants or bounds is abandoned (via an exception, or for an extended_return_statement, via an exit or goto statement), and then a return statement with the “right” discriminants or bounds is executed. The only solution for this problem is to not have the permission at all, but this is too unusual of a case to worry about the effects of the permission, especially given the implementation difficulties for built-in-place objects that this permission is intended to ease.
- 24.d/3 {AI05-0050-1} Note that the mutable-discriminant case only happens when built-in-place initialization is optional. This means that any difficulties associated with implementing built-in-place initialization without these permissions can be sidestepped by not building in place.

Examples

- 25 *Examples of return statements:*
- 26/2 {AI95-00318-02} **return;** -- in a procedure body, entry_body,
-- accept_statement, or extended_return_statement
- 27 **return** Key_Value (Last_Index); -- in a function body
- 28/2 {AI95-00318-02} **return** Node : Cell **do** -- in a function body, see 3.10.1 for Cell
 Node.Value := Result;
 Node.Succ := Next_Node;
end return;

Incompatibilities With Ada 83

- 28.a/2 {AI95-00318-02} In Ada 95, if the result type of a function has a part that is a task, then an attempt to return a local variable will raise Program_Error. This is illegal in Ada 2005, see below. In Ada 83, if a function returns a local variable containing a task, execution is erroneous according to AI83-00867. However, there are other situations where functions that return tasks (or that return a variant record only one of whose variants includes a task) are correct in Ada 83 but will raise Program_Error according to the new rules.
- 28.b The rule change was made because there will be more types (protected types, limited controlled types) in Ada 95 for which it will be meaningless to return a local variable, and making all of these erroneous is unacceptable. The current rule was felt to be the simplest that kept upward incompatibilities to situations involving returning tasks, which are quite rare.

Wording Changes from Ada 83

- 28.c/3 {AI05-0299-1} This subclause has been moved here from chapter 5, since it has mainly to do with subprograms.
- 28.d A function now creates an anonymous object. This is necessary so that controlled types will work.
- 28.e/2 {AI95-00318-02} We have clarified that a return statement applies to a callable construct, not to a callable entity.
- 28.f/2 {AI95-00318-02} There is no need to mention generics in the rules about where a return statement can appear and what it applies to; the phrase “body of a subprogram or generic subprogram” is syntactic, and refers exactly to “subprogram_body”.

Inconsistencies With Ada 95

- 28.f.1/3 {AI95-0416-1} {AI05-0005-1} {AI05-0050-1} Added an Implementation Permission allowing early raising of Constraint_Error if the result cannot fit in the ultimate object. This gives implementations more flexibility to do built-in-place returns, and is essential for limited types (which cannot be built in a temporary). However, it allows raising Constraint_Error in some cases where it would not be raised if the permission was not used. See Inconsistencies With Ada 2005 for additional changes. This case is potentially inconsistent with Ada 95, but a compiler does not have to take advantage of these permissions for any Ada 95 code, so there should be little practical impact.

Incompatibilities With Ada 95

- 28.g/2 {AI95-00318-02} The entire business about return-by-reference types has been dropped. Instead, the expression of a return statement of a limited type can only be an aggregate or function_call (see 7.5). This means that returning a global object or type_conversion, legal in Ada 95, is now illegal. Such functions can be converted to use anonymous

access return types by adding **access** in the function definition and return statement, adding **.all** in uses, and adding **aliased** in the object declarations. This has the advantage of making the reference return semantics much clearer to the casual reader.

We changed these rules so that functions, combined with the new rules for limited types (7.5), can be used as build-in-place constructors for limited types. This reduces the differences between limited and nonlimited types, which will make limited types useful in more circumstances. 28.h/2

Extensions to Ada 95

{AI95-00318-02} The **extended_return_statement** is new. This provides a name for the object being returned, which reduces the copying needed to return complex objects (including no copying at all for limited objects). It also allows component-by-component construction of the return object. 28.i/2

Wording Changes from Ada 95

{AI95-00318-02} The wording was updated to support anonymous access return subtypes. 28.j/2

{AI95-00318-02} The term “return expression” was dropped because reviewers found it confusing when applied to the default expression of an **extended_return_statement**. 28.k/2

{AI95-00344-01} {AI95-00416-01} Added accessibility checks to class-wide return statements. These checks could not fail in Ada 95 (as all of the types had to be declared at the same level, so the tagged type would necessarily have been at the same level as the type of the object). 28.l/2

{AI95-00402-01} {AI95-00416-01} Added accessibility checks to return statements for types with access discriminants. Since such types have to be limited in Ada 95, the expression of a return statement would have been illegal in order for this check to fail. 28.m/2

Inconsistencies With Ada 2005

{AI05-0050-1} **Correction:** The Implementation Permission allowing early raising of **Constraint_Error** was modified to remove the most common of these cases from the permission (returning an object with mutable discriminants, where the return object is created with one set of discriminants and then changed to another). (The permission was also widened to allow the early check for constrained functions when that constraint is wrong.) However, there still is an unlikely case where the permission would allow an exception to be raised when none would be raised by the canonical semantics (when a return statement is abandoned). These changes can only remove the raising of an exception (or change the place where it is raised) compared to Ada 2005, so programs that depend on the previous behavior should be very rare. 28.n/3

{AI05-0051-1} {AI05-0234-1} **Correction:** Accessibility checks for access discriminants now depend on the master of the call rather than the point of declaration of the function. This will result in cases that used to raise **Program_Error** now running without raising any exception. This is technically inconsistent with Ada 2005 (as defined by Amendment 1), but it is unlikely that any real code depends on the raising of this exception. 28.o/3

{AI05-0073-1} **Correction:** Added a tag check for functions returning anonymous access-to-tagged types, so that dispatching of tag-indeterminate function works as expected. This is technically inconsistent with Ada 2005 (as defined by Amendment 1), but as the feature in question was newly added to Ada 2005, there should be little code that depends on the behavior that now raises an exception. 28.p/3

Incompatibilities With Ada 2005

{AI05-0053-1} {AI05-0277-1} **Correction:** The **aliased** keyword can now only appear on extended return objects with an immutably limited type. Other types would provide a way to get an aliased view of an object that is not necessarily aliased, which would be very bad. This is incompatible, but since the feature was added in Ada 2005, the keyword had no defined meaning in Ada 2005 (a significant oversight), and most sensible uses involve immutably limited types, it is unlikely that it appears meaningfully in existing programs. 28.q/3

{AI05-0103-1} **Correction:** Added wording to require static matching for unconstrained access types in extended return statements. This disallows adding or omitting null exclusions, and adding access constraints, in the declaration of the return object. While this is incompatible, the incompatible cases in question are either useless (access constraints – the constraint can be given on an **allocator** if necessary, and still must be given there even if given on the return object) or wrong (null exclusions – null could be returned from a function declared to be null excluding), so we expect them to be extremely rare in practice. 28.r/3

Extensions to Ada 2005

{AI05-0015-1} {AI05-0144-2} The return object of an **extended_return_statement** can be declared constant; this works similarly to a constant object declaration. 28.s/3

- 28.t/3 {AI05-0032-1} Added wording to allow the `return_subtype_indication` to have a specific type if the return subtype of the function is class-wide. Specifying the (specific) type of the return object is awkward without this change, and this is consistent with the way `allocators` work.

Wording Changes from Ada 2005

- 28.u/3 {AI05-0024-1} **Correction:** Corrected the master check for tags since the masters may be for different tasks and thus incomparable.
- 28.v/3 {AI05-0058-1} **Correction:** Corrected the wording defining returns for `extended_return_statements`, since leaving by an exit or goto is considered “normal” completion of the statement.
- 28.w/3 {AI05-0205-1} {AI05-0277-1} **Correction:** Added the `extended_return_object_declaration` to make other rules easier to write and eliminate the problem described in AI05-0205-1.

6.5.1 Nonreturning Procedures

- 1/3 {AI95-00329-01} {AI95-00414-01} {AI05-0229-1} Specifying aspect `No_Return` to have the value `True` indicates that a procedure cannot return normally[; it may propagate an exception or loop forever].

- 1.a/3 **Discussion:** Aspect `No_Deposit` will have to wait for Ada 2020. :-)

Paragraphs 2 and 3 were moved to Annex J, “Obsolescent Features”.

Static Semantics

- 3.1/3 {AI05-0229-1} For a procedure or generic procedure, the following language-defined representation aspect may be specified:
- 3.2/3 `No_Return` The type of aspect `No_Return` is Boolean. When aspect `No_Return` is `True` for an entity, the entity is said to be *nonreturning*.
- 3.3/3 If directly specified, the `aspect_definition` shall be a static expression. [This aspect is never inherited;] if not directly specified, the aspect is `False`.
- 3.a/3 **Aspect Description for `No_Return`:** A procedure will not return normally.
- 3.4/3 {AI05-0229-1} If a generic procedure is nonreturning, then so are its instances. If a procedure declared within a generic unit is nonreturning, then so are the corresponding copies of that procedure in instances.

Legality Rules

- 4/3 {AI95-00329-01} {AI95-00414-01} {AI05-0229-1} Aspect `No_Return` shall not be specified for a null procedure nor an instance of a generic unit.
- 4.a/2 **Reason:** A null procedure cannot have the appropriate nonreturning semantics, as it does not raise an exception or loop forever.
- 4.b/3 **Ramification:** {AI05-0229-1} The procedure can be abstract. If a nonreturning procedure is renamed (anywhere) calls through the new name still have the nonreturning semantics.
- 5/2 {AI95-00329-01} {AI95-00414-01} A return statement shall not apply to a nonreturning procedure or generic procedure.
- 6/2 {AI95-00414-01} A procedure shall be nonreturning if it overrides a dispatching nonreturning procedure. In addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit.
- 6.a/2 **Reason:** This ensures that dispatching calls to nonreturning procedures will, in fact, not return.
- 7/2 {AI95-00414-01} If a renaming-as-body completes a nonreturning procedure declaration, then the renamed procedure shall be nonreturning.
- 7.a/2 **Reason:** This ensures that no extra code is needed to implement the renames (that is, no wrapper is needed) as the body has the same property.

Paragraph 8 was deleted.

Dynamic Semantics

{AI95-00329-01} {AI95-00414-01} If the body of a nonreturning procedure completes normally, Program_Error is raised at the point of the call. 9/2

Discussion: Note that there is no name for suppressing this check, since the check represents a bug, imposes no time overhead, and minimal space overhead (since it can usually be statically eliminated as dead code). 9.a/2

Implementation Note: If a nonreturning procedure tries to return, we raise Program_Error. This is stated as happening at the call site, because we do not wish to allow the procedure to handle the exception (and then, perhaps, try to return again!). However, the expected run-time model is that the compiler will generate **raise** Program_Error at the end of the procedure body (but not handleable by the procedure itself), as opposed to doing it at the call site. (This is just like the typical run-time model for functions that fall off the end without returning a value). The reason is indirect calls: in P.all(...);, the compiler cannot know whether P designates a nonreturning procedure or a normal one. Putting the **raise** Program_Error in the procedure's generated code solves this problem neatly. 9.b/2

Similarly, if one passes a nonreturning procedure to a generic formal parameter, the compiler cannot know this at call sites (in shared code implementations); the raise-in-body solution deals with this neatly. 9.c/2

Examples

```
{AI95-00433-01} {AI05-0229-1} procedure Fail(Msg : String)  -- raises Fatal_Error exception 10/3
with No_Return;
-- Inform compiler and reader that procedure never returns normally
```

Extensions to Ada 95

{AI95-00329-01} {AI95-00414-01} Pragma No_Return is new. 10.a/2

Extensions to Ada 2005

{AI05-0229-1} Aspect No_Return is new; pragma No_Return is now obsolescent. 10.b/3

6.6 Overloading of Operators

An *operator* is a function whose designator is an operator_symbol. [Operators, like other functions, may be overloaded.] 1

Name Resolution Rules

Each use of a unary or binary operator is equivalent to a function_call with function_prefix being the corresponding operator_symbol, and with (respectively) one or two positional actual parameters being the operand(s) of the operator (in order). 2

To be honest: {AI05-0299-1} We also use the term operator (in Clause 4 and in 6.1) to refer to one of the syntactic categories defined in 4.5, “Operators and Expression Evaluation” whose names end with “_operator:” logical_operator, relational_operator, binary_adding_operator, unary_adding_operator, multiplying_operator, and highest_precedence_operator. 2.a/3

Discussion: {AI05-0005-1} This equivalence extends to uses of function_call in most other language rules. However, as often happens, the equivalence is not perfect, as operator calls are not a name, while a function_call is a name. Thus, operator calls cannot be used in contexts that require a name (such as a rename of an object). A direct fix for this problem would be very disruptive, and thus we have not done that. However, qualifying an operator call can be used as a workaround in contexts that require a name. 2.b/3

Legality Rules

{AI05-0143-1} The subprogram_specification of a unary or binary operator shall have one or two parameters, respectively. The parameters shall be of mode **in**. A generic function instantiation whose designator is an operator_symbol is only allowed if the specification of the generic function has the corresponding number of parameters, and they are all of mode **in**. 3/3

- 4 Default_expressions are not allowed for the parameters of an operator (whether the operator is declared with an explicit subprogram_specification or by a generic_instantiation).
- 5 An explicit declaration of "/"= shall not have a result type of the predefined type Boolean.

Static Semantics

6/3 {AI05-0128-1} An explicit declaration of "=" whose result type is Boolean implicitly declares an operator "/"= that gives the complementary result.

6.a/3 **Discussion:** {AI05-0128-1} A "/"= defined by this rule is considered user-defined, which means that it will be inherited by a derived type. “User-defined” means “not language-defined” for the purposes of inheritance, that is anything other than predefined operators.

NOTES

- 7 8 The operators "+" and "-" are both unary and binary operators, and hence may be overloaded with both one- and two-parameter functions.

Examples

8 *Examples of user-defined operators:*

```
9 function "+" (Left, Right : Matrix) return Matrix;
function "+" (Left, Right : Vector) return Vector;
```

```
-- assuming that A, B, and C are of the type Vector
-- the following two statements are equivalent:
```

```
A := B + C;
A := "+" (B, C);
```

Extensions to Ada 83

- 9.a Explicit declarations of "=" are now permitted for any combination of parameter and result types.
- 9.b Explicit declarations of "/"= are now permitted, so long as the result type is not Boolean.

Wording Changes from Ada 2005

- 9.c/3 {AI05-0128-1} **Correction:** Corrected the wording so that only explicit declarations of "=" cause an implicit declaration of "/"=; otherwise, we could get multiple implicit definitions of "/"= without an obvious way to chose between them.
- 9.d/3 {AI05-0143-1} Added wording so that operators only allow parameters of mode **in**. This was made necessary by the elimination elsewhere of the restriction that function parameters be only of mode **in**.

6.7 Null Procedures

- 1/2 {AI95-00348-01} A null_procedure_declaration provides a shorthand to declare a procedure with an empty body.

Syntax

```
2/3 {AI95-00348-01} {AI05-0183-1} null_procedure_declaration ::=
  [overriding_indicator]
  procedure_specification is null
  [aspect_specification];
```

Legality Rules

- 2.1/3 {AI05-0177-1} If a null_procedure_declaration is a completion, it shall be the completion of a subprogram_declaration or generic_subprogram_declaration. The profile of a null_procedure_declaration that completes a declaration shall conform fully to that of the declaration.

Static Semantics

{AI95-00348-01} {AI05-0177-1} {AI05-0264-1} A `null_procedure_declaration` declares a *null procedure*. A completion is not allowed for a `null_procedure_declaration`; however, a `null_procedure_declaration` can complete a previous declaration. 3/3

Reason: There are no null functions because the return value has to be constructed somehow; a function that always raises `Program_Error` doesn't seem very useful or worth the complication. 3.a/2

Dynamic Semantics

{AI95-00348-01} The execution of a null procedure is invoked by a subprogram call. For the execution of a subprogram call on a null procedure, the execution of the `subprogram_body` has no effect. 4/2

Ramification: Thus, a null procedure is equivalent to the body 4.a/2

```
begin
  null;
end;
```

4.b/2

with the exception that a null procedure can be used in place of a procedure specification. 4.c/2

{AI95-00348-01} {AI05-0177-1} The elaboration of a `null_procedure_declaration` has no other effect than to establish that the null procedure can be called without failing the `Elaboration_Check`. 5/3

Examples

{AI95-00433-01} `procedure Simplify(Expr : in out Expression) is null; -- see 3.9`
-- By default, Simplify does nothing, but it may be overridden in extensions of Expression 6/2

Extensions to Ada 95

{AI95-00348-01} Null procedures are new. 6.a/2

Extensions to Ada 2005

{AI05-0177-1} A `null_procedure_declaration` can now be a completion. 6.b/3

{AI05-0183-1} An optional `aspect_specification` can be used in a `null_procedure_declaration`. This is described in 13.1.1. 6.c/3

6.8 Expression Functions

{AI05-0177-1} An `expression_function_declaration` provides a shorthand to declare a function whose body consists of a single return statement. 1/3

Syntax

```
{AI95-0177-1} expression_function_declaration ::=
  [overriding_indicator]
  function_specification is
    (expression)
    [aspect_specification];
```

2/3

Name Resolution Rules

{AI05-0177-1} The expected type for the expression of an `expression_function_declaration` is the result type (see 6.5) of the function. 3/3

Legality Rules

{AI05-0177-1} If an `expression_function_declaration` is a completion, it shall be the completion of a `subprogram_declaration` or `generic_subprogram_declaration`. The profile of an `expression_function_declaration` that completes a declaration shall conform fully to that of the declaration. 4/3

5/3 {AI05-0177-1} If the result subtype has one or more unconstrained access discriminants, the accessibility level of the anonymous access type of each access discriminant, as determined by the expression of the expression function, shall not be statically deeper than that of the master that elaborated the `expression_function_declaration`.

5.a/3 **Ramification:** This can only fail if the discriminant is an access to a part of a non-aliased parameter, as there can be no local declarations here.

5.b/3 **Discussion:** We don't need to repeat any of the other Legality Rules for return statements since none of them can fail here: the implicit return statement has to apply to this function (and isn't nested in something), there clearly is a return statement in this function, and the static classwide accessibility check cannot fail as a tagged type cannot be declared locally in an expression function.

Static Semantics

6/3 {AI05-0177-1} {AI05-0264-1} An `expression_function_declaration` declares an *expression function*. A completion is not allowed for an `expression_function_declaration`; however, an `expression_function_declaration` can complete a previous declaration.

Dynamic Semantics

7/3 {AI05-0177-1} {AI05-0262-1} The execution of an expression function is invoked by a subprogram call. For the execution of a subprogram call on an expression function, the execution of the `subprogram_body` executes an implicit function body containing only a `simple_return_statement` whose expression is that of the expression function.

7.a/3 **Discussion:** The last sentence effectively means that all of the dynamic wording in 6.5 applies as needed, and we don't have to repeat it here.

8/3 {AI05-0177-1} The elaboration of an `expression_function_declaration` has no other effect than to establish that the expression function can be called without failing the `Elaboration_Check`.

Examples

9/3 {AI05-0177-1} `function Is-Origin (P : in Point) return Boolean is -- see 3.9
(P.X = 0.0 and P.Y = 0.0);`

Extensions to Ada 2005

9.a/3 {AI05-0177-1} Expression functions are new in Ada 2012.

7 Packages

[Packages are program units that allow the specification of groups of logically related entities. Typically, a package contains the declaration of a type (often a private type or private extension) along with the declarations of primitive subprograms of the type, which can be called from outside the package, while their inner workings remain hidden from outside users.] 1

7.1 Package Specifications and Declarations

[A package is generally provided in two parts: a `package_specification` and a `package_body`. Every package has a `package_specification`, but not all packages have a `package_body`.] 1

Syntax

```
package_declaration ::= package_specification; 2
{AI05-0183-1} package_specification ::= 3/3
  package defining_program_unit_name
    [aspect_specification] is
      {basic_declarative_item}
  [private
    {basic_declarative_item}]
  end [[parent_unit_name.]identifier]
```

If an identifier or `parent_unit_name.identifier` appears at the end of a `package_specification`, then this sequence of lexical elements shall repeat the `defining_program_unit_name`. 4

Legality Rules

{AI95-00434-01} A `package_declaration` or `generic_package_declaration` requires a completion [(a body)] if it contains any `basic_declarative_item` that requires a completion, but whose completion is not in its `package_specification`. 5/2

To be honest: {AI05-0229-1} If an implementation supports it, the body of a package or generic package may be imported (using aspect `Import`, see B.1), in which case no explicit body is allowed. 5.a/3

Static Semantics

{AI95-00420-01} {AI95-00434-01} The first list of `basic_declarative_items` of a `package_specification` of a package other than a generic formal package is called the *visible part* of the package. [The optional list of `basic_declarative_items` after the reserved word **private** (of any `package_specification`) is called the *private part* of the package. If the reserved word **private** does not appear, the package has an implicit empty private part.] Each list of `basic_declarative_items` of a `package_specification` forms a *declaration list* of the package. 6/2

Ramification: This definition of visible part does not apply to generic formal packages — 12.7 defines the visible part of a generic formal package. 6.a

The implicit empty private part is important because certain implicit declarations occur there if the package is a child package, and it defines types in its visible part that are derived from, or contain as components, private types declared within the parent package. These implicit declarations are visible in children of the child package. See 10.1.1. 6.b

[An entity declared in the private part of a package is visible only within the declarative region of the package itself (including any child units — see 10.1.1). In contrast, expanded names denoting entities declared in the visible part can be used even outside the package; furthermore, direct visibility of such entities can be achieved by means of `use_clauses` (see 4.1.3 and 8.4).] 7

Dynamic Semantics

8 The elaboration of a `package_declaration` consists of the elaboration of its `basic_declarative_items` in the given order.

NOTES

- 9 1 The visible part of a package contains all the information that another program unit is able to know about the package.
- 10 2 If a declaration occurs immediately within the specification of a package, and the declaration has a corresponding completion that is a body, then that body has to occur immediately within the body of the package.
- 10.a **Proof:** This follows from the fact that the declaration and completion are required to occur immediately within the same declarative region, and the fact that `bodies` are disallowed (by the Syntax Rules) in `package_specifications`. This does not apply to instances of generic units, whose bodies can occur in `package_specifications`.

Examples

11 *Example of a package declaration:*

```

12 package Rational_Numbers is
13     type Rational is
14         record
15             Numerator    : Integer;
16             Denominator  : Positive;
17         end record;
18     function "=" (X,Y : Rational) return Boolean;
19     function "/" (X,Y : Integer) return Rational; -- to construct a rational number
20     function "+" (X,Y : Rational) return Rational;
21     function "-" (X,Y : Rational) return Rational;
22     function "*" (X,Y : Rational) return Rational;
23     function "/" (X,Y : Rational) return Rational;
24 end Rational_Numbers;
```

17 There are also many examples of package declarations in the predefined language environment (see Annex A).

Incompatibilities With Ada 83

- 17.a In Ada 83, a library package is allowed to have a body even if it doesn't need one. In Ada 95, a library package body is either required or forbidden — never optional. The workaround is to add `pragma Elaborate_Body`, or something else requiring a body, to each library package that has a body that isn't otherwise required.

Wording Changes from Ada 83

- 17.b/3 {AI05-0299-1} We have moved the syntax into this subclause and the next subclause from RM83-7.1, “Package Structure”, which we have removed.
- 17.c RM83 was unclear on the rules about when a package requires a body. For example, RM83-7.1(4) and RM83-7.1(8) clearly forgot about the case of an incomplete type declared in a `package_declaration` but completed in the body. In addition, RM83 forgot to make this rule apply to a generic package. We have corrected these rules. Finally, since we now allow a `pragma Import` for any explicit declaration, the completion rules need to take this into account as well.

Wording Changes from Ada 95

- 17.d/2 {AI95-00420-01} Defined “declaration list” to avoid ambiguity in other rules as to whether packages are included.

Extensions to Ada 2005

- 17.e/3 {AI05-0183-1} An optional `aspect_specification` can be used in a `package_specification`. This is described in 13.1.1.

7.2 Package Bodies

1 [In contrast to the entities declared in the visible part of a package, the entities declared in the `package_body` are visible only within the `package_body` itself. As a consequence, a package with a

`package_body` can be used for the construction of a group of related subprograms in which the logical operations available to clients are clearly isolated from the internal entities.]

Syntax

```
{AI05-0267-1} package_body ::= 2/3
  package body defining_program_unit_name
    [aspect_specification] is
    declarative_part
  [begin
    handled_sequence_of_statements]
  end [[parent_unit_name.]identifier];
```

If an identifier or `parent_unit_name.identifier` appears at the end of a `package_body`, then this sequence of lexical elements shall repeat the `defining_program_unit_name`. 3

Legality Rules

A `package_body` shall be the completion of a previous `package_declaration` or `generic_package_declaration`. A library `package_declaration` or library `generic_package_declaration` shall not have a body unless it requires a body[; **pragma** `Elaborate_Body` can be used to require a library `unit_declaration` to have a body (see 10.2.1) if it would not otherwise require one]. 4

Ramification: The first part of the rule forbids a `package_body` from standing alone — it has to belong to some previous `package_declaration` or `generic_package_declaration`. 4.a

A nonlibrary `package_declaration` or nonlibrary `generic_package_declaration` that does not require a completion may have a corresponding body anyway. 4.b

Static Semantics

{AI05-0299-1} In any `package_body` without statements there is an implicit `null_statement`. For any `package_declaration` without an explicit completion, there is an implicit `package_body` containing a single `null_statement`. For a noninstance, nonlibrary package, this body occurs at the end of the `declarative_part` of the innermost enclosing program unit or `block_statement`; if there are several such packages, the order of the implicit `package_bodies` is unspecified. [(For an instance, the implicit `package_body` occurs at the place of the instantiation (see 12.3). For a library package, the place is partially determined by the elaboration dependences (see Clause 10).)] 5/3

Discussion: Thus, for example, we can refer to something happening just after the **begin** of a `package_body`, and we can refer to the `handled_sequence_of_statements` of a `package_body`, without worrying about all the optional pieces. The place of the implicit body makes a difference for tasks activated by the package. See also RM83-9.3(5). 5.a

The implicit body would be illegal if explicit in the case of a library package that does not require (and therefore does not allow) a body. This is a bit strange, but not harmful. 5.b

Dynamic Semantics

For the elaboration of a nongeneric `package_body`, its `declarative_part` is first elaborated, and its `handled_sequence_of_statements` is then executed. 6

NOTES

3 A variable declared in the body of a package is only visible within this body and, consequently, its value can only be changed within the `package_body`. In the absence of local tasks, the value of such a variable remains unchanged between calls issued from outside the package to subprograms declared in the visible part. The properties of such a variable are similar to those of a “static” variable of C. 7

4 The elaboration of the body of a subprogram explicitly declared in the visible part of a package is caused by the elaboration of the body of the package. Hence a call of such a subprogram by an outside program unit raises the exception `Program_Error` if the call takes place before the elaboration of the `package_body` (see 3.11). 8

Examples

9 *Example of a package body (see 7.1):*

```

10 package body Rational_Numbers is
11     procedure Same_Denominator (X,Y : in out Rational) is
12         begin
13             -- reduces X and Y to the same denominator:
14             ...
15         end Same_Denominator;
16     function "=" (X,Y : Rational) return Boolean is
17         U : Rational := X;
18         V : Rational := Y;
19         begin
20             Same_Denominator (U,V);
21             return U.Numerator = V.Numerator;
22         end "=";
23     function "/" (X,Y : Integer) return Rational is
24         begin
25             if Y > 0 then
26                 return (Numerator => X, Denominator => Y);
27             else
28                 return (Numerator => -X, Denominator => -Y);
29             end if;
30         end "/";
31     function "+" (X,Y : Rational) return Rational is ... end "+";
32     function "-" (X,Y : Rational) return Rational is ... end "-";
33     function "*" (X,Y : Rational) return Rational is ... end "*";
34     function "/" (X,Y : Rational) return Rational is ... end "/";
35 end Rational_Numbers;
```

Wording Changes from Ada 83

- 15.a The syntax rule for `package_body` now uses the syntactic category `handled_sequence_of_statements`.
- 15.b The `declarative_part` of a `package_body` is now required; that doesn't make any real difference, since a `declarative_part` can be empty.
- 15.c RM83 seems to have forgotten to say that a `package_body` can't stand alone, without a previous declaration. We state that rule here.
- 15.d RM83 forgot to restrict the definition of elaboration of `package_bodies` to nongeneric ones. We have corrected that omission.
- 15.e The rule about implicit bodies (from RM83-9.3(5)) is moved here, since it is more generally applicable.

Extensions to Ada 2005

- 15.f/3 {AI05-0267-1} An optional `aspect_specification` can be used in a `package_body`. This is described in 13.1.1.

7.3 Private Types and Private Extensions

- 1 [The declaration (in the visible part of a package) of a type as a private type or private extension serves to separate the characteristics that can be used directly by outside program units (that is, the logical properties) from other characteristics whose direct use is confined to the package (the details of the definition of the type itself). See 3.9.1 for an overview of type extensions.]

Language Design Principles

- 1.a A private (untagged) type can be thought of as a record type with the type of its single (hidden) component being the full view.
- 1.b A private tagged type can be thought of as a private extension of an anonymous parent with no components. The only dispatching operation of the parent is equality (although the `Size` attribute, and, if nonlimited, assignment are allowed, and those will presumably be implemented in terms of dispatching).

Syntax

{AI05-0183-1} private_type_declaration ::= 2/3
type defining_identifier [discriminant_part] **is** [[**abstract**] **tagged**] [**limited**] **private**
 [aspect_specification];

{AI95-00251-01} *{AI95-00419-01}* *{AI95-00443-01}* *{AI05-0183-1}* 3/3
 private_extension_declaration ::=
type defining_identifier [discriminant_part] **is**
 [**abstract**] [**limited** | **synchronized**] **new** ancestor_subtype_indication
 [**and** interface_list] **with private**
 [aspect_specification];

Legality Rules

A private_type_declaration or private_extension_declaration declares a *partial view* of the type; such a 4
 declaration is allowed only as a declarative_item of the visible part of a package, and it requires a
 completion, which shall be a full_type_declaration that occurs as a declarative_item of the private part of
 the package. [The view of the type declared by the full_type_declaration is called the *full view*.] A
 generic formal private type or a generic formal private extension is also a partial view.

To be honest: A private type can also be imported (using aspect Import, see B.1), in which case no completion is 4.a
 allowed, if supported by an implementation.

Reason: We originally used the term “private view,” but this was easily confused with the view provided *from* the 4.b
 private part, namely the full view.

Proof: *{AI95-00326-01}* Full view is now defined in 3.2.1, “Type Declarations”, as all types now have them. 4.c/2

[A type shall be completely defined before it is frozen (see 3.11.1 and 13.14). Thus, neither the 5
 declaration of a variable of a partial view of a type, nor the creation by an allocator of an object of the
 partial view are allowed before the full declaration of the type. Similarly, before the full declaration, the
 name of the partial view cannot be used in a generic_instantiation or in a representation item.]

Proof: This rule is stated officially in 3.11.1, “Completions of Declarations”. 5.a

{AI95-00419-01} *{AI95-00443-01}* [A private type is limited if its declaration includes the reserved word 6/2
limited; a private extension is limited if its ancestor type is a limited type that is not an interface type, or
 if the reserved word **limited** or **synchronized** appears in its definition.] If the partial view is nonlimited,
 then the full view shall be nonlimited. If a tagged partial view is limited, then the full view shall be
 limited. [On the other hand, if an untagged partial view is limited, the full view may be limited or
 nonlimited.]

If the partial view is tagged, then the full view shall be tagged. [On the other hand, if the partial view is 7
 untagged, then the full view may be tagged or untagged.] In the case where the partial view is untagged
 and the full view is tagged, no derivatives of the partial view are allowed within the immediate scope of
 the partial view; [derivatives of the full view are allowed.]

Ramification: Note that deriving from a partial view within its immediate scope can only occur in a package that is a 7.a
 child of the one where the partial view is declared. The rule implies that in the visible part of a public child package, it
 is impossible to derive from an untagged private type declared in the visible part of the parent package in the case
 where the full view of the parent type turns out to be tagged. We considered a model in which the derived type was
 implicitly redeclared at the earliest place within its immediate scope where characteristics needed to be added.
 However, we rejected that model, because (1) it would imply that (for an untagged type) subprograms explicitly
 declared after the derived type could be inherited, and (2) to make this model work for composite types as well, several
 implicit redeclarations would be needed, since new characteristics can become visible one by one; that seemed like too
 much mechanism.

Discussion: The rule for tagged partial views is redundant for partial views that are private extensions, since all 7.b
 extensions of a given ancestor tagged type are tagged, and limited if the ancestor is limited. We phrase this rule
 partially redundantly to keep its structure parallel with the other rules.

- 7.c **To be honest:** This rule is checked in a generic unit, rather than using the “assume the best” or “assume the worst” method.
- 7.d/2 **Reason:** *{AI95-00230-01}* Tagged limited private types have certain capabilities that are incompatible with having assignment for the full view of the type. In particular, tagged limited private types can be extended with components of a limited type, which works only because assignment is not allowed. Consider the following example:
- 7.e
- ```

package P1 is
 type T1 is tagged limited private;
 procedure Foo(X : in T1'Class);
private
 type T1 is tagged null record; -- Illegal!
 -- This should say "tagged limited null record".
end P1;

```
- 7.f/1
- ```

package body P1 is
  type A is access T1'Class;
  Global : A;
  procedure Foo(X : in T1'Class) is
  begin
    Global := new T1'Class'(X);
    -- This would be illegal if the full view of
    -- T1 were limited, like it's supposed to be.
  end Foo;
end P1;

```
- 7.g/2
- ```

{AI95-00230-01} with P1;
package P2 is
 type T2(D : access Integer)
 is new P1.T1 with
 record
 My_Task : Some_Task_Type; -- Trouble!
 end record;
end P2;

```
- 7.h/1
- ```

with P1;
with P2;
procedure Main is
  Local : aliased Integer;
  Y : P2.T2(D => Local'Access);
begin
  P1.Foo(Y);
end Main;

```
- 7.i/2 *{AI95-00230-01}* If the above example were legal, we would have succeeded in doing an assignment of a task object, which is supposed to be a no-no.
- 7.j This rule is not needed for private extensions, because they inherit their limitedness from their ancestor, and there is a separate rule forbidding limited components of the corresponding record extension if the parent is nonlimited.
- 7.k **Ramification:** A type derived from an untagged private type is untagged, even if the full view of the parent is tagged, and even at places that can see the parent:
- 7.l
- ```

package P is
 type Parent is private;
private
 type Parent is tagged
 record
 X: Integer;
 end record;
end P;

```
- 7.m/1
- ```

with P;
package Q is
  type T is new P.Parent;
end Q;

```
- 7.n
- ```

with Q; use Q;
package body P is
 ... T'Class ... -- Illegal!
 Object: T;
 ... Object.X ... -- Illegal!
 ... Parent(Object).X ... -- OK.
end P;

```
- 7.o The declaration of T declares an untagged view. This view is always untagged, so T'Class is illegal, it would be illegal to extend T, and so forth. The component name X is never visible for this view, although the component is still there — one can get one's hands on it via a `type_conversion`.

{AI95-00396-01} If a full type has a partial view that is tagged, then: 7.1/2

- the partial view shall be a synchronized tagged type (see 3.9.4) if and only if the full type is a synchronized tagged type; 7.2/2

**Reason:** Since we do not allow record extensions of synchronized tagged types, this property has to be visible in the partial view to avoid privacy breaking. Generic formals do not need a similar rule as any extensions are rechecked for legality in the specification, and extensions of tagged formals are always illegal in a generic body. 7.o.1/2

- the partial view shall be a descendant of an interface type (see 3.9.4) if and only if the full type is a descendant of the interface type. 7.3/2

**Reason:** Consider the following example: 7.p/2

```

package P is
 package Pkg is
 type Ifc is interface;
 procedure Foo (X : Ifc) is abstract;
 end Pkg;
 type Parent_1 is tagged null record;
 type T1 is new Parent_1 with private;
private
 type Parent_2 is new Parent_1 and Pkg.Ifc with null record;
 procedure Foo (X : Parent_2); -- Foo #1
 type T1 is new Parent_2 with null record; -- Illegal.
end P;
with P;
package P_Client is
 type T2 is new P.T1 and P.Pkg.Ifc with null record;
 procedure Foo (X : T2); -- Foo #2
 X : T2;
end P_Client;
with P_Client;
package body P is
 ...
 procedure Bar (X : T1'Class) is
 begin
 Pkg.Foo (X); -- should call Foo #1 or an override thereof
 end;
begin
 Pkg.Foo (Pkg.Ifc'Class (P_Client.X)); -- should call Foo #2
 Bar (T1'Class (P_Client.X));
end P;

```

This example is illegal because the completion of T1 is descended from an interface that the partial view is not descended from. If it were legal, T2 would implement Ifc twice, once in the visible part of P, and once in the visible part of P\_Client. We would need to decide how Foo #1 and Foo #2 relate to each other. There are two options: either Foo #2 overrides Foo #1, or it doesn't. 7.y/2

If Foo #2 overrides Foo #1, we have a problem because the client redefines a behavior that it doesn't know about, and we try to avoid this at all costs, as it would lead to a breakdown of whatever abstraction was implemented. If the abstraction didn't expose that it implements Ifc, there must be a reason, and it should be able to depend on the fact that no overriding takes place in clients. Also, during maintenance, things may change and the full view might implement a different set of interfaces. Furthermore, the situation is even worse if the full type implements another interface Ifc2 that happens to have a conforming Foo (otherwise unrelated, except for its name and profile). 7.z/2

If Foo #2 doesn't override Foo #1, there is some similarity with the case of normal tagged private types, where a client can declare an operation that happens to conform to some private operation, and that's OK, it gets a different slot in the type descriptor. The problem here is that T2 would implement Ifc in two different ways, and through conversions to Ifc'Class we could end up with visibility on both of these two different implementations. This is the “diamond inheritance” problem of C++ all over again, and we would need some kind of a preference rule to pick one implementation. We don't want to go there (if we did, we might as well provide full-fledged multiple inheritance). 7.aa/2

Note that there wouldn't be any difficulty to implement the first option, so the restriction is essentially methodological. The second option might be harder to implement, depending on the language rules that we would choose. 7.bb/2

**Ramification:** {AI05-0005-1} This rule also prevents completing a private type with an interface. An interface, like all types, is a descendant of itself, and thus this rule is triggered. One reason this is necessary is that a client of a private extension should be able to inherit limitedness without having to look in the private part to see if the type is an interface (remember that limitedness of interfaces is never inherited, while it is inherited from other types). 7.cc/3

- 8 The *ancestor subtype* of a `private_extension_declaration` is the subtype defined by the *ancestor\_subtype\_indication*; the ancestor type shall be a specific tagged type. The full view of a private extension shall be derived (directly or indirectly) from the ancestor type. In addition to the places where Legality Rules normally apply (see 12.3), the requirement that the ancestor be specific applies also in the private part of an instance of a generic unit.
- 8.a **Reason:** This rule allows the full view to be defined through several intermediate derivations, possibly from a series of types produced by `generic_instantiations`.
- 8.1/2 {AI95-00419-01} {AI95-00443-01} If the reserved word **limited** appears in a `private_extension_declaration`, the ancestor type shall be a limited type. If the reserved word **synchronized** appears in a `private_extension_declaration`, the ancestor type shall be a limited interface.
- 9 If the declaration of a partial view includes a `known_discriminant_part`, then the `full_type_declaration` shall have a fully conforming [(explicit)] `known_discriminant_part` [(see 6.3.1, “Conformance Rules”)]. [The ancestor subtype may be unconstrained; the parent subtype of the full view is required to be constrained (see 3.7).]
- 9.a **Discussion:** If the ancestor subtype has discriminants, then it is usually best to make it unconstrained.
- 9.b **Ramification:** If the partial view has a `known_discriminant_part`, then the full view has to be a composite, non-array type, since only such types may have known discriminants. Also, the full view cannot inherit the discriminants in this case; the `known_discriminant_part` has to be explicit.
- 9.c That is, the following is illegal:
- 9.d 

```
package P is
 type T(D : Integer) is private;
private
 type T is new Some_Other_Type; -- Illegal!
end P;
```
- 9.e even if `Some_Other_Type` has an integer discriminant called `D`.
- 9.f It is a ramification of this and other rules that in order for a tagged type to privately inherit unconstrained discriminants, the private type declaration has to have an `unknown_discriminant_part`.
- 10 If a private extension inherits known discriminants from the ancestor subtype, then the full view shall also inherit its discriminants from the ancestor subtype, and the parent subtype of the full view shall be constrained if and only if the ancestor subtype is constrained.
- 10.a **Reason:** The first part ensures that the full view has the same discriminants as the partial view. The second part ensures that if the partial view is unconstrained, then the full view is also unconstrained; otherwise, a client might constrain the partial view in a way that conflicts with the constraint on the full view.
- 10.1/3 {AI95-00419-01} {AI05-0004-1} If the `full_type_declaration` for a private extension includes a `derived_type_definition`, then the reserved word **limited** shall appear in the `full_type_declaration` if and only if it also appears in the `private_extension_declaration`.
- 10.b/3 **Reason:** {AI05-0004-1} The word **limited** is optional (unless the ancestor is an interface), but it should be used consistently. Otherwise things would be too confusing for the reader. Of course, we only require that if the full type includes a `derived_type_definition`, as we want to allow task and protected types to complete extensions of synchronized interfaces.
- 11 [If a partial view has unknown discriminants, then the `full_type_declaration` may define a definite or an indefinite subtype, with or without discriminants.]
- 12 If a partial view has neither known nor unknown discriminants, then the `full_type_declaration` shall define a definite subtype.
- 13 If the ancestor subtype of a private extension has constrained discriminants, then the parent subtype of the full view shall impose a statically matching constraint on those discriminants.

**Ramification:** If the parent type of the full view is not the ancestor type, but is rather some descendant thereof, the constraint on the discriminants of the parent type might come from the declaration of some intermediate type in the derivation chain between the ancestor type and the parent type. 13.a

**Reason:** This prevents the following: 13.b

```
package P is
 type T2 is new T1(Discrim => 3) with private;
private
 type T2 is new T1(Discrim => 999) -- Illegal!
 with record ...;
end P; 13.c
```

The constraints in this example do not statically match. 13.d

If the constraint on the parent subtype of the full view depends on discriminants of the full view, then the ancestor subtype has to be unconstrained: 13.e

```
type One_Discrim(A: Integer) is tagged ...;
...
package P is
 type Two_Discrims(B: Boolean; C: Integer) is new One_Discrim with private;
private
 type Two_Discrims(B: Boolean; C: Integer) is new One_Discrim(A => C) with
 record
 ...
 end record;
end P; 13.f
```

The above example would be illegal if the private extension said “is new One\_Discrim(A => C);”, because then the constraints would not statically match. (Constraints that depend on discriminants are not static.) 13.g

#### Static Semantics

A `private_type_declaration` declares a private type and its first subtype. Similarly, a `private_extension_declaration` declares a private extension and its first subtype. 14

**Discussion:** A *package-private type* is one declared by a `private_type_declaration`; that is, a private type other than a generic formal private type. Similarly, a *package-private extension* is one declared by a `private_extension_declaration`. These terms are not used in the RM95 version of this document. 14.a

{AI05-0269-1} A declaration of a partial view and the corresponding `full_type_declaration` define two views of a single type. The declaration of a partial view together with the visible part define the operations that are available to outside program units; the declaration of the full view together with the private part define other operations whose direct use is possible only within the declarative region of the package itself. Moreover, within the scope of the declaration of the full view, the characteristics (see 3.4) of the type are determined by the full view; in particular, within its scope, the full view determines the classes that include the type, which components, entries, and protected subprograms are visible, what attributes and other predefined operations are allowed, and whether the first subtype is static. See 7.3.1. 15/3

{AI95-00401-01} {AI05-0110-1} For a private extension, the characteristics (including components, but excluding discriminants if there is a new `discriminant_part` specified), predefined operators, and inherited user-defined primitive subprograms are determined by its ancestor type and its progenitor types (if any), in the same way that those of a record extension are determined by those of its parent type and its progenitor types (see 3.4 and 7.3.1). 16/3

**To be honest:** {AI05-0110-1} If an operation of the ancestor or parent type is abstract, then the abstractness of the inherited operation is different for nonabstract record extensions than for nonabstract private extensions (see 3.9.3). 16.a/3

#### Dynamic Semantics

The elaboration of a `private_type_declaration` creates a partial view of a type. The elaboration of a `private_extension_declaration` elaborates the *ancestor\_subtype\_indication*, and creates a partial view of a type. 17

#### NOTES

5 The partial view of a type as declared by a `private_type_declaration` is defined to be a composite view (in 3.2). The full view of the type might or might not be composite. A private extension is also composite, as is its full view. 18

- 19/2 6 {AI95-00318-02} Declaring a private type with an `unknown_discriminant_part` is a way of preventing clients from creating uninitialized objects of the type; they are then forced to initialize each object by calling some operation declared in the visible part of the package.
- 19.a **Discussion:** Packages with private types are analogous to generic packages with formal private types, as follows: The declaration of a package-private type is like the declaration of a formal private type. The visible part of the package is like the generic formal part; these both specify a contract (that is, a set of operations and other things available for the private type). The private part of the package is like an instantiation of the generic; they both give a `full_type_declaration` that specifies implementation details of the private type. The clients of the package are like the body of the generic; usage of the private type in these places is restricted to the operations defined by the contract.
- 19.b In other words, being inside the package is like being outside the generic, and being outside the package is like being inside the generic; a generic is like an “inside-out” package.
- 19.c This analogy also works for private extensions in the same inside-out way.
- 19.d Many of the legality rules are defined with this analogy in mind. See, for example, the rules relating to operations of [formal] derived types.
- 19.e The completion rules for a private type are intentionally quite similar to the matching rules for a generic formal private type.
- 19.f This analogy breaks down in one respect: a generic actual subtype is a subtype, whereas the full view for a private type is always a new type. (We considered allowing the completion of a `private_type_declaration` to be a `subtype_declaration`, but the semantics just won't work.) This difference is behind the fact that a generic actual type can be class-wide, whereas the completion of a private type always declares a specific type.
- 20/2 7 {AI95-00401} The ancestor type specified in a `private_extension_declaration` and the parent type specified in the corresponding declaration of a record extension given in the private part need not be the same. If the ancestor type is not an interface type, the parent type of the full view can be any descendant of the ancestor type. In this case, for a primitive subprogram that is inherited from the ancestor type and not overridden, the formal parameter names and default expressions (if any) come from the corresponding primitive subprogram of the specified ancestor type, while the body comes from the corresponding primitive subprogram of the parent type of the full view. See 3.9.2.
- 20.1/2 8 {AI95-00401} If the ancestor type specified in a `private_extension_declaration` is an interface type, the parent type can be any type so long as the full view is a descendant of the ancestor type. The progenitor types specified in a `private_extension_declaration` and the progenitor types specified in the corresponding declaration of a record extension given in the private part need not be the same — the only requirement is that the private extension and the record extension be descended from the same set of interfaces.

#### *Examples*

21 *Examples of private type declarations:*

```
22 type Key is private;
23 type File_Name is limited private;
```

23 *Example of a private extension declaration:*

```
24 type List is new Ada.Finalization.Controlled with private;
```

#### *Extensions to Ada 83*

- 24.a The syntax for a `private_type_declaration` is augmented to allow the reserved word **tagged**.
- 24.b In Ada 83, a private type without discriminants cannot be completed with a type with discriminants. Ada 95 allows the full view to have discriminants, so long as they have defaults (that is, so long as the first subtype is definite). This change is made for uniformity with generics, and because the rule as stated is simpler and easier to remember than the Ada 83 rule. In the original version of Ada 83, the same restriction applied to generic formal private types. However, the restriction was removed by the ARG for generics. In order to maintain the “generic contract/private type contract analogy” discussed above, we have to apply the same rule to package-private types. Note that a private untagged type without discriminants can be completed with a tagged type with discriminants only if the full view is constrained, because discriminants of tagged types cannot have defaults.

#### *Wording Changes from Ada 83*

- 24.c RM83-7.4.1(4), “Within the specification of the package that declares a private type and before the end of the corresponding full type declaration, a restriction applies...”, is subsumed (and corrected) by the rule that a type shall be completely defined before it is frozen, and the rule that the parent type of a derived type declaration shall be completely defined, unless the derived type is a private extension.

*Extensions to Ada 95*

{AI95-00251-01} {AI95-00396-01} {AI95-00401-01} Added `interface_list` to private extensions to support interfaces and multiple inheritance (see 3.9.4). 24.d/2

{AI95-00419-01} A private extension may specify that it is a limited type. This is required for interface ancestors (from which limitedness is not inherited), but it is generally useful as documentation of limitedness. 24.e/2

{AI95-00443-01} A private extension may specify that it is a synchronized type. This is required in order so that a regular limited interface can be used as the ancestor of a synchronized type (we do not allow hiding of synchronization). 24.f/2

*Extensions to Ada 2005*

{AI05-0183-1} An optional `aspect_specification` can be used in a `private_type_declaration` and a `private_extension_declaration`. This is described in 13.1.1. 24.g/3

*Wording Changes from Ada 2005*

{AI05-0110-1} **Correction:** The description of how a private extension inherits characteristics was made consistent with the way formal derived types inherit characteristics (see 12.5.1). 24.h/3

### 7.3.1 Private Operations

[For a type declared in the visible part of a package or generic package, certain operations on the type do not become visible until later in the package — either in the private part or the body. Such *private operations* are available only inside the declarative region of the package or generic package.] 1

*Static Semantics*

The predefined operators that exist for a given type are determined by the classes to which the type belongs. For example, an integer type has a predefined "+" operator. In most cases, the predefined operators of a type are declared immediately after the definition of the type; the exceptions are explained below. Inherited subprograms are also implicitly declared immediately after the definition of the type, except as stated below. 2

{8652/0019} {AI95-00033-01} {AI05-0029-1} For a composite type, the characteristics (see 7.3) of the type are determined in part by the characteristics of its component types. At the place where the composite type is declared, the only characteristics of component types used are those characteristics visible at that place. If later immediately within the declarative region in which the composite type is declared additional characteristics become visible for a component type, then any corresponding characteristics become visible for the composite type. Any additional predefined operators are implicitly declared at that place. If there is no such place, then additional predefined operators are not declared at all, but they still exist. 3/3

**Reason:** {AI05-0029-1} We say that the predefined operators exist because they can emerge in some unusual generic instantiations. See 12.5. 3.a/3

**Discussion:** {AI05-0029-1} The predefined operators for the underlying class of a type always exist, even if there is no visibility on that underlying class. This rule is simply about where (if ever) those operators are declared (and thus become usable). The “additional predefined operators” defined by this rule are any that are not declared at the point of the original type declaration. For instance, a type derived from a private type whose full type is type `String` always will have a ">" operator, but where that operator is declared (and thus whether it is visible) will depend on the visibility of the full type of the parent type. 3.b/3

{8652/0019} {AI95-00033-01} The corresponding rule applies to a type defined by a `derived_type_definition`, if there is a place immediately within the declarative region in which the type is declared where additional characteristics of its parent type become visible. 4/1

{8652/0019} {AI95-00033-01} [For example, an array type whose component type is limited private becomes nonlimited if the full view of the component type is nonlimited and visible at some later place 5/1

immediately within the declarative region in which the array type is declared. In such a case, the predefined "=" operator is implicitly declared at that place, and assignment is allowed after that place.]

5.1/3 {AI05-0115-1} {AI05-0269-1} A type is a *descendant* of the full view of some ancestor of its parent type only if the current view it has of its parent is a descendant of the full view of that ancestor. More generally, at any given place, a type is descended from the same view of an ancestor as that from which the current view of its parent is descended. This view determines what characteristics are inherited from the ancestor[, and, for example, whether the type is considered to be a descendant of a record type, or a descendant only through record extensions of a more distant ancestor].

5.2/3 {AI05-0115-1} [It is possible for there to be places where a derived type is visibly a descendant of an ancestor type, but not a descendant of even a partial view of the ancestor type, because the parent of the derived type is not visibly a descendant of the ancestor. In this case, the derived type inherits no characteristics from that ancestor, but nevertheless is within the derivation class of the ancestor for the purposes of type conversion, the "covers" relationship, and matching against a formal derived type. In this case the derived type is considered to be a *descendant* of an incomplete view of the ancestor.]

5.a.1/3 **Discussion:** Here is an example of this situation:

```
5.a.2/3 package P is
 type T is private;
 C : constant T;
 private
 type T is new Integer;
 C : constant T := 42;
 end P;
5.a.3/3 with P;
 package Q is
 type T2 is new P.T;
 end Q;
5.a.4/3 with Q;
 package P.Child is
 type T3 is new Q.T2;
 private
 Int : Integer := 52;
 V : T3 := T3(P.C); -- Legal: conversion allowed
 W : T3 := T3(Int); -- Legal: conversion allowed
 X : T3 := T3(42); -- Error: T3 is not a numeric type
 Y : T3 := X + 1; -- Error: no visible "+" operator
 Z : T3 := T3(Integer(W) + 1); -- Legal: convert to Integer first
 end P.Child;
```

6/3 {8652/0019} {AI95-00033-01} {AI05-0029-1} Inherited primitive subprograms follow a different rule. For a *derived\_type\_definition*, each inherited primitive subprogram is implicitly declared at the earliest place, if any, immediately within the declarative region in which the *type\_declaration* occurs, but after the *type\_declaration*, where the corresponding declaration from the parent is visible. If there is no such place, then the inherited subprogram is not declared at all, but it still exists. [For a tagged type, it is possible to dispatch to an inherited subprogram that is not declared at all.]

7 For a *private\_extension\_declaration*, each inherited subprogram is declared immediately after the *private\_extension\_declaration* if the corresponding declaration from the ancestor is visible at that place. Otherwise, the inherited subprogram is not declared for the private extension, [though it might be for the full type].

7.a/1 **Reason:** There is no need for the "earliest place immediately within the declarative region" business here, because a *private\_extension\_declaration* will be completed with a *full\_type\_declaration*, so we can hang the necessary private implicit declarations on the *full\_type\_declaration*.

7.b **Discussion:** The above rules matter only when the component type (or parent type) is declared in the visible part of a package, and the composite type (or derived type) is declared within the declarative region of that package (possibly in a nested package or a child package).

| Another_Int does not inherit Int_Op, because Int_Op does not “exist” at the place where Another_Int is declared.                                                                                                                                                                                                                                          | 7.l   |
| Type T2 inherits Op1 and Op2 from Root. However, the inherited Op2 is never declared, because Parent.Op2 is never visible immediately within the declarative region of T2. T2 explicitly declares its own Op2, but this is unrelated to the inherited one — it does not override the inherited one, and occupies a different slot in the type descriptor. | 7.m/1 |
| T3 inherits both Op1 and Op2. Op1 is implicitly declared immediately after the type declaration, whereas Op2 is declared at the beginning of the private part. Note that if Child were a private child of Parent, then Op1 and Op2 would both be implicitly declared immediately after the type declaration.                                              | 7.n   |
| T4 is similar to T3, except that the earliest place immediately within the declarative region containing T4 where Root's Op2 is visible is in the body of Nested.                                                                                                                                                                                         | 7.o/1 |
| If T3 or T4 were to declare a type-conformant Op2, this would override the one inherited from Root. This is different from the situation with T2.                                                                                                                                                                                                         | 7.p   |
| T5 inherits Op1 and two Op2's from T2. Op1 is implicitly declared immediately after the declaration of T5, as is the Op2 that came from Unrelated.Op2. However, the Op2 that originally came from Parent.Op2 is never implicitly declared for T5, since T2's version of that Op2 is never visible (anywhere — it never got declared either).              | 7.q   |
| For all of these rules, implicit private parts and bodies are assumed as needed.                                                                                                                                                                                                                                                                          | 7.r   |
| It is possible for characteristics of a type to be revealed in more than one place:                                                                                                                                                                                                                                                                       | 7.s   |

- ```

package body P.Q is
 package body R is
 -- Things like "xor"(A,A) return A are implicitly
 -- declared here.
 end R;
end P.Q;

```
- 7.v.1/1 {8652/0019} {AI95-00033-01} We say *immediately* within the declarative region in order that types do not gain operations within a nested scope. Consider:
- 7.v.2/1
- ```

package Outer is
  package Inner is
    type Inner_Type is private;
  private
    type Inner_Type is new Boolean;
  end Inner;
  type Outer_Type is array(Natural range <>) of Inner.Inner_Type;
end Outer;

```
- 7.v.3/1
- ```

package body Outer is
 package body Inner is
 -- At this point, we can see that Inner_Type is a Boolean type.
 -- But we don't want Outer_Type to gain an "and" operator here.
 end Inner;
end Outer;

```
- 8 [The Class attribute is defined for tagged subtypes in 3.9. In addition,] for every subtype S of an untagged private type whose full view is tagged, the following attribute is defined:
- 9 S'Class Denotes the class-wide subtype corresponding to the full view of S. This attribute is allowed only from the beginning of the private part in which the full view is declared, until the declaration of the full view. [After the full view, the Class attribute of the full view can be used.]
- NOTES
- 10 9 Because a partial view and a full view are two different views of one and the same type, outside of the defining package the characteristics of the type are those defined by the visible part. Within these outside program units the type is just a private type or private extension, and any language rule that applies only to another class of types does not apply. The fact that the full declaration might implement a private type with a type of a particular class (for example, as an array type) is relevant only within the declarative region of the package itself including any child units.
- 11 The consequences of this actual implementation are, however, valid everywhere. For example: any default initialization of components takes place; the attribute Size provides the size of the full view; finalization is still done for controlled components of the full view; task dependence rules still apply to components that are task objects.
- 12/2 10 {AI95-00287-01} Partial views provide initialization, membership tests, selected components for the selection of discriminants and inherited components, qualification, and explicit conversion. Nonlimited partial views also allow use of assignment\_statements.
- 13 11 For a subtype S of a partial view, S'Size is defined (see 13.3). For an object A of a partial view, the attributes A'Size and A'Address are defined (see 13.3). The Position, First\_Bit, and Last\_Bit attributes are also defined for discriminants and inherited components.

## Examples

Example of a type with private operations:

```

package Key_Manager is
 type Key is private;
 Null_Key : constant Key; -- a deferred constant declaration (see 7.4)
 procedure Get_Key(K : out Key);
 function "<" (X, Y : Key) return Boolean;
private
 type Key is new Natural;
 Null_Key : constant Key := Key'First;
end Key_Manager;

package body Key_Manager is
 Last_Key : Key := Null_Key;
 procedure Get_Key(K : out Key) is
 begin
 Last_Key := Last_Key + 1;
 K := Last_Key;
 end Get_Key;

 function "<" (X, Y : Key) return Boolean is
 begin
 return Natural(X) < Natural(Y);
 end "<";
end Key_Manager;

```

## NOTES

12 *Notes on the example:* Outside of the package `Key_Manager`, the operations available for objects of type `Key` include assignment, the comparison for equality or inequality, the procedure `Get_Key` and the operator `"<"`; they do not include other relational operators such as `">="`, or arithmetic operators. 18

The explicitly declared operator `"<"` hides the predefined operator `"<"` implicitly declared by the `full_type_declaration`. Within the body of the function, an explicit conversion of `X` and `Y` to the subtype `Natural` is necessary to invoke the `"<"` operator of the parent type. Alternatively, the result of the function could be written as `not (X >= Y)`, since the operator `">="` is not redefined. 19

The value of the variable `Last_Key`, declared in the package body, remains unchanged between calls of the procedure `Get_Key`. (See also the NOTES of 7.2.) 20

*Wording Changes from Ada 83*

The phrase in RM83-7.4.2(7), "...after the full type declaration", doesn't work in the presence of child units, so we define that rule in terms of visibility. 20.a

The definition of the Constrained attribute for private types has been moved to "Obsolescent Features." (The Constrained attribute of an object has not been moved there.) 20.b

*Wording Changes from Ada 95*

{8652/0018} {AI95-00033-01} **Corrigendum:** Clarified when additional operations are declared. 20.c/2

{AI95-00287-01} Revised the note on operations of partial views to reflect that limited types do have an assignment operation, but not `assignment_statements`. 20.d/2

*Wording Changes from Ada 2005*

{AI05-0029-1} **Correction:** Revised the wording to say that predefined operations still exist even if they are never declared, because it is possible to reference them in a generic unit. 20.e/3

{AI05-0115-1} **Correction:** Clarified that the characteristics of a descendant of a private type depend on the visibility of the full view of the direct ancestor. This has to be the case (so that privacy is not violated), but it wasn't spelled out in earlier versions of Ada. 20.f/3

## 7.3.2 Type Invariants

{AI05-0146-1} For a private type or private extension, the following language-defined aspects may be specified with an `aspect_specification` (see 13.1.1): 1/3

2/3 {AI05-0146-1} {AI05-0250-1} Type\_Invariant  
 This aspect shall be specified by an expression, called an *invariant expression*. Type\_Invariant may be specified on a `private_type_declaration`, on a `private_extension_declaration`, or on a `full_type_declaration` that declares the completion of a private type or private extension.

2.a/3 **Aspect Description for Type\_Invariant:** A condition that must hold true for all objects of a type.

3/3 {AI05-0146-1} Type\_Invariant'Class  
 This aspect shall be specified by an expression, called an *invariant expression*. Type\_Invariant'Class may be specified on a `private_type_declaration` or a `private_extension_declaration`.

3.a/3 **Reason:** {AI05-0254-1} A class-wide type invariant cannot be hidden in the private part, as the creator of an extension needs to know about it in order to conform to it in any new or overriding operations. On the other hand, a specific type invariant is not inherited, so that no operation outside of the original package needs to conform to it; thus there is no need for it to be visible.

3.b/3 **Aspect Description for Type\_Invariant'Class:** A condition that must hold true for all objects in a class of types.

#### *Name Resolution Rules*

4/3 {AI05-0146-1} The expected type for an invariant expression is any boolean type.

5/3 {AI05-0146-1} [Within an invariant expression, the identifier of the first subtype of the associated type denotes the current instance of the type.] Within an invariant expression associated with type *T*, the type of the current instance is *T* for the Type\_Invariant aspect and *T*'Class for the Type\_Invariant'Class aspect.

5.a/3 **Proof:** The first sentence is given formally in 13.1.1.

#### *Legality Rules*

6/3 {AI05-0146-1} [The Type\_Invariant'Class aspect shall not be specified for an untagged type.] The Type\_Invariant aspect shall not be specified for an abstract type.

6.a/3 **Proof:** The first sentence is given formally in 13.1.1.

#### *Static Semantics*

7/3 {AI05-0250-1} [If the Type\_Invariant aspect is specified for a type *T*, then the invariant expression applies to *T*.]

8/3 {AI05-0146-1} [If the Type\_Invariant'Class aspect is specified for a tagged type *T*, then the invariant expression applies to all descendants of *T*.]

8.a/3 **Proof:** "Applies" is formally defined in 13.1.1.

#### *Dynamic Semantics*

9/3 {AI05-0146-1} {AI05-0247-1} {AI05-0290-1} If one or more invariant expressions apply to a type *T*, then an invariant check is performed at the following places, on the specified object(s):

10/3 • After successful default initialization of an object of type *T*, the check is performed on the new object;

11/3 • After successful conversion to type *T*, the check is performed on the result of the conversion;

12/3 • {AI05-0146-1} {AI05-0269-1} For a view conversion, outside the immediate scope of *T*, that converts from a descendant of *T* (including *T* itself) to an ancestor of type *T* (other than *T* itself), a check is performed on the part of the object that is of type *T*:

13/3 • after assigning to the view conversion; and

14/3 • after successful return from a call that passes the view conversion as an **in out** or **out** parameter.

- Ramification:** For a single view conversion that converts between distantly related types, this rule could be triggered for multiple types and thus multiple invariant checks may be needed. 14.a/3
- Implementation Note:** {AI05-0299-1} For calls to inherited subprograms (including dispatching calls), the implied view conversions mean that a wrapper is probably needed. (See the Note at the bottom of this subclause for more on the model of checks for inherited subprograms.) 14.b/3
- For view conversions involving class-wide types, the exact checks needed may not be known at compile-time. One way to deal with this is to have an implicit dispatching operation that is given the object to check and the tag of the target of the conversion, and which first checks if the passed tag is not for itself, and if not, checks the its invariant on the object and then calls the operation of its parent type. If the tag is for itself, the operation is complete. 14.c/3
- After a successful call on the Read or Input stream attribute of the type *T*, the check is performed on the object initialized by the stream attribute; 15/3
  - {AI05-0146-1} {AI05-0269-1} An invariant is checked upon successful return from a call on any subprogram or entry that: 16/3
    - {AI05-0146-1} {AI05-0269-1} is declared within the immediate scope of type *T* (or by an instance of a generic unit, and the generic is declared within the immediate scope of type *T*), and 17/3
    - is visible outside the immediate scope of type *T* or overrides an operation that is visible outside the immediate scope of *T*, and 18/3
    - {AI05-0289-1} has a result with a part of type *T*, or one or more parameters with a part of type *T*, or an access to variable parameter whose designated type has a part of type *T*. 19/3
- {AI05-0146-1} {AI05-0269-1} The check is performed on each such part of type *T*. 20/3
- {AI05-0290-1} If performing checks is required by the Invariant or Invariant'Class assertion policies (see 11.4.2) in effect at the point of corresponding aspect specification applicable to a given type, then the respective invariant expression is considered *enabled*. 21/3
- Ramification:** If a class-wide invariant expression is enabled for a type, it remains enabled when inherited by descendants of that type, even if the policy in effect is Ignore for the inheriting type. 21.a/3
- {AI05-0146-1} {AI05-0250-1} {AI05-0289-1} {AI05-0290-1} The invariant check consists of the evaluation of each enabled invariant expression that applies to *T*, on each of the objects specified above. If any of these evaluate to False, Assertions.Assertion\_Error is raised at the point of the object initialization, conversion, or call. If a given call requires more than one evaluation of an invariant expression, either for multiple objects of a single type or for multiple types with invariants, the evaluations are performed in an arbitrary order, and if one of them evaluates to False, it is not specified whether the others are evaluated. Any invariant check is performed prior to copying back any by-copy **in out** or **out** parameters. Invariant checks, any postcondition check, and any constraint or predicate checks associated with **in out** or **out** parameters are performed in an arbitrary order. 22/3
- {AI05-0146-1} {AI05-0247-1} {AI05-0250-1} The invariant checks performed on a call are determined by the subprogram or entry actually invoked, whether directly, as part of a dispatching call, or as part of a call through an access-to-subprogram value. 23/3
- Ramification:** Invariant checks on subprogram return are not performed on objects that are accessible only through access values. It is also possible to call through an access-to-subprogram value and reach a subprogram body that has visibility on the full declaration of a type, from outside the immediate scope of the type. No invariant checks will be performed if the designated subprogram is not itself externally visible. These cases represent "holes" in the protection provided by invariant checks; but note that these holes cannot be caused by clients of the type *T* with the invariant without help for the designer of the package containing *T*. 23.a/3
- Implementation Note:** The implementation might want to produce a warning if a private extension has an ancestor type that is a visible extension, and an invariant expression depends on the value of one of the components from a visible extension part. 23.b/3

## NOTES

- 24/3 13 {AI05-0250-1} {AI05-0269-1} For a call of a primitive subprogram of type *NT* that is inherited from type *T*, the specified checks of the specific invariants of both the types *NT* and *T* are performed. For a call of a primitive subprogram of type *NT* that is overridden for type *NT*, the specified checks of the specific invariants of only type *NT* are performed.
- 24.a/3 **Proof:** This follows from the definition of a call on an inherited subprogram as view conversions of the parameters of the type and a call to the original subprogram (see 3.4), along with the normal invariant checking rules. In particular, the call to the original subprogram takes care of any checks needed on type *T*, and the checks required on view conversions take care of any checks needed on type *NT*, specifically on **in out** and **out** parameters. We require this in order that the semantics of an explicitly defined wrapper that does nothing but call the original subprogram is the same as that of an inherited subprogram.

*Extensions to Ada 2005*

- 24.b/3 {AI05-0146-1} {AI05-0247-1} {AI05-0250-1} {AI05-0289-1} Type\_Invariant aspects are new.

## 7.4 Deferred Constants

- 1 [Deferred constant declarations may be used to declare constants in the visible part of a package, but with the value of the constant given in the private part. They may also be used to declare constants imported from other languages (see Annex B).]

*Legality Rules*

- 2/3 {AI05-0229-1} {AI05-0269-1} [ A *deferred constant declaration* is an `object_declaration` with the reserved word **constant** but no initialization expression.] The constant declared by a deferred constant declaration is called a *deferred constant*. [Unless the Import aspect (see B.1) is True for a deferred constant declaration, the ] deferred constant declaration requires a completion, which shall be a full constant declaration (called the *full declaration* of the deferred constant).
- 2.a **Proof:** The first sentence is redundant, as it is stated officially in 3.3.1.
- 2.b/3 {AI05-0229-1} {AI05-0269-1} The first part of the last sentence is redundant, as no imported entity may have a completion, as stated in B.1.
- 3 A deferred constant declaration that is completed by a full constant declaration shall occur immediately within the visible part of a `package_specification`. For this case, the following additional rules apply to the corresponding full declaration:
- 4 • The full declaration shall occur immediately within the private part of the same package;
- 5/2 • {AI95-00385-01} The deferred and full constants shall have the same type, or shall have statically matching anonymous access subtypes;
- 5.a/2 **Ramification:** {AI95-00385-01} This implies that both the deferred declaration and the full declaration have to have a `subtype_indication` or `access_definition` rather than an `array_type_definition`, because each `array_type_definition` would define a new type.
- 6/3 • {AI95-00385-01} {AI05-0062-1} {AI05-0262-1} If the deferred constant declaration includes a `subtype_indication` *S* that defines a constrained subtype, then the constraint defined by the `subtype_indication` in the full declaration shall match the constraint defined by *S* statically.[ On the other hand, if the subtype of the deferred constant is unconstrained, then the full declaration is still allowed to impose a constraint. The constant itself will be constrained, like all constants;]
- 7/2 • {AI95-00231-01} If the deferred constant declaration includes the reserved word **aliased**, then the full declaration shall also;
- 7.a **Ramification:** On the other hand, the full constant can be aliased even if the deferred constant is not.
- 7.1/2 • {AI95-00231-01} If the subtype of the deferred constant declaration excludes null, the subtype of the full declaration shall also exclude null.

- Ramification:** On the other hand, the full constant can exclude null even if the deferred constant does not. But that can only happen for a `subtype_indication`, as anonymous access types are required to statically match (which includes any `null_exclusion`). 7.a.1/2
- {AI05-0229-1} [A deferred constant declaration for which the `Import` aspect is `True` need not appear in the visible part of a `package_specification`, and has no full constant declaration.] 8/3
- {AI95-00256-01} The completion of a deferred constant declaration shall occur before the constant is frozen (see 13.14). 9/2

*Dynamic Semantics*

- {AI05-0004-1} The elaboration of a deferred constant declaration elaborates the `subtype_indication`, `access_definition`, or (only allowed in the case of an imported constant) the `array_type_definition`. 10/3
- Ramification:** {AI05-0004-1} For nonimported constants, these elaborations cannot require any code or checks for a legal program, because the given `subtype_indication` has to be indefinite or statically match that of the full constant, meaning that either it is a `subtype_mark` or it has static constraints. If the deferred constant instead has an `access_definition`, the designated subtype must be a `subtype_mark`. We still say that these are elaborated, however, because part of elaboration is creating the type, which is clearly needed for `access_definitions`. (A deferred constant and its full constant have different types when they are specified by an `access_definition`, although there is no visible effect of these types being different as neither can be named.) 10.a/3

## NOTES

- 14 The full constant declaration for a deferred constant that is of a given private type or private extension is not allowed before the corresponding `full_type_declaration`. This is a consequence of the freezing rules for types (see 13.14). 11
- Ramification:** Multiple or single declarations are allowed for the deferred and the full declarations, provided that the equivalent single declarations would be allowed. 11.a
- Deferred constant declarations are useful for declaring constants of private views, and types with components of private views. They are also useful for declaring access-to-constant objects that designate variables declared in the private part of a package. 11.b

*Examples*

- Examples of deferred constant declarations:* 12
- ```
Null_Key : constant Key;           -- see 7.3.1 13
```
- ```
{AI05-0229-1} CPU_Identifier : constant String(1..8) 14/3
 with Import => True, Convention => Assembler, Link_Name => "CPU_ID";
 -- see B.1
```

*Extensions to Ada 83*

- In Ada 83, a deferred constant is required to be of a private type declared in the same visible part. This restriction is removed for Ada 95; deferred constants can be of any type. 14.a
- In Ada 83, a deferred constant declaration was not permitted to include a constraint, nor the reserved word **aliased**. 14.b
- In Ada 83, the rules required conformance of type marks; here we require static matching of subtypes if the deferred constant is constrained. 14.c
- A deferred constant declaration can be completed with a `pragma Import`. Such a deferred constant declaration need not be within a `package_specification`. 14.d
- The rules for too-early uses of deferred constants are modified in Ada 95 to allow more cases, and catch all errors at compile time. This change is necessary in order to allow deferred constants of a tagged type without violating the principle that for a dispatching call, there is always an implementation to dispatch to. It has the beneficial side effect of catching some Ada-83-erroneous programs at compile time. The new rule fits in well with the new freezing-point rules. Furthermore, we are trying to convert undefined-value problems into bounded errors, and we were having trouble for the case of deferred constants. Furthermore, uninitialized deferred constants cause trouble for the shared variable / tasking rules, since they are really variable, even though they purport to be constant. In Ada 95, they cannot be touched until they become constant. 14.e
- Note that we do not consider this change to be an upward incompatibility, because it merely changes an erroneous execution in Ada 83 into a compile-time error. 14.f

- 14.g The Ada 83 semantics are unclear in the case where the full view turns out to be an access type. It is a goal of the language design to prevent uninitialized access objects. One wonders if the implementation is required to initialize the deferred constant to null, and then initialize it (again!) to its real value. In Ada 95, the problem goes away.

*Wording Changes from Ada 83*

- 14.h/3 {AI05-0299-1} Since deferred constants can now be of a nonprivate type, we have made this a stand-alone subclause, rather than a subclause of 7.3, “Private Types and Private Extensions”.
- 14.i Deferred constant declarations used to have their own syntax, but now they are simply a special case of `object_declarations`.

*Extensions to Ada 95*

- 14.j/2 {AI95-00385-01} Deferred constants were enhanced to allow the use of anonymous access types in them.

*Wording Changes from Ada 95*

- 14.k/2 {AI95-00231-01} Added matching rules for subtypes that exclude null.

*Wording Changes from Ada 2005*

- 14.l/3 {AI05-0062-1} **Correction:** Corrected rules so that the intent that a full constant may have a null exclusion even if the deferred constant does not is actually met.

## 7.5 Limited Types

- 1/2 {AI95-00287-01} [A limited type is (a view of) a type for which copying (such as for an `assignment_statement`) is not allowed. A nonlimited type is a (view of a) type for which copying is allowed.]
- 1.a **Discussion:** The concept of the *value* of a limited type is difficult to define, since the abstract value of a limited type often extends beyond its physical representation. In some sense, values of a limited type cannot be divorced from their object. The value *is* the object.
- 1.b/2 {AI95-00318-02} In Ada 83, in the two places where limited types were defined by the language, namely tasks and files, an implicit level of indirection was implied by the semantics to avoid the separation of the value from an associated object. In Ada 95, most limited types are passed by reference, and even return-ed by reference. In Ada 2005, most limited types are built-in-place upon return, rather than returned by reference. Thus the object “identity” is part of the logical value of most limited types.
- 1.c/2 **To be honest:** {AI95-00287-01} {AI95-00419-01} For a limited partial view whose full view is nonlimited, copying is possible on parameter passing and function return. To prevent any copying whatsoever, one should make both the partial *and* full views limited.
- 1.d/2 **Glossary entry:** A limited type is a type for which copying (such as in an `assignment_statement`) is not allowed. A nonlimited type is a type for which copying is allowed.

*Legality Rules*

- 2/2 {AI95-00419-01} If a tagged record type has any limited components, then the reserved word **limited** shall appear in its `record_type_definition`. [If the reserved word **limited** appears in the definition of a `derived_type_definition`, its parent type and any progenitor interfaces shall be limited.]
- 2.a.1/2 **Proof:** {AI95-00419-01} The rule about the parent type being required to be limited can be found in 3.4. Rules about progenitor interfaces can be found in 3.9.4, specifically, a nonlimited interface can appear only on a nonlimited type. We repeat these rules here to gather these scattered rules in one obvious place.
- 2.a **Reason:** This prevents tagged limited types from becoming nonlimited. Otherwise, the following could happen:

```

package P is
 type T is limited private;
 type R is tagged
 record -- Illegal!
 -- This should say "limited record".
 X : T;
 end record;
private
 type T is new Integer; -- R becomes nonlimited here.
end P;
package Q is
 type R2 is new R with
 record
 Y : Some_Task_Type;
 end record;
end Q;

```

{AI95-00230-01} If the above were legal, then assignment would be defined for R'Class in the body of P, which is bad news, given the task. 2.d/2

{AI95-00287-01} {AI95-00318-02} {AI05-0147-1} In the following contexts, an expression of a limited type is not permitted unless it is an aggregate, a function\_call, a parenthesized expression or qualified\_expression whose operand is permitted by this rule, or a conditional\_expression all of whose dependent\_expressions are permitted by this rule: 2.1/3

- the initialization expression of an object\_declaration (see 3.3.1) 2.2/2
- the default\_expression of a component\_declaration (see 3.8) 2.3/2
- the expression of a record\_component\_association (see 4.3.1) 2.4/2
- the expression for an ancestor\_part of an extension\_aggregate (see 4.3.2) 2.5/2
- an expression of a positional\_array\_aggregate or the expression of an array\_component\_association (see 4.3.3) 2.6/2
- the qualified\_expression of an initialized allocator (see 4.8) 2.7/2
- the expression of a return statement (see 6.5) 2.8/2
- {AI05-0177-1} the expression of an expression\_function\_declaration (see 6.8) 2.9/3
- the default\_expression or actual parameter for a formal object of mode in (see 12.4) 2.10/3

**Discussion:** All of these contexts normally require copying; by restricting the uses as above, we can require the new object to be built-in-place. 2.e/2

#### Static Semantics

{AI95-00419-01} {AI05-0178-1} A view of a type is *limited* if it is one of the following: 3/3

- {AI95-00411-01} {AI95-00419-01} a type with the reserved word **limited**, **synchronized**, **task**, or **protected** in its definition; 4/2
  - **Ramification:** Note that there is always a “definition,” conceptually, even if there is no syntactic category called “...\_definition”. 4.a
  - {AI95-00419-01} This includes interfaces of the above kinds, derived types with the reserved word **limited**, as well as task and protected types. 4.b/2
- {AI95-00419-01} {AI05-0087-1} a class-wide type whose specific type is limited; 5/3
- {AI95-00419-01} a composite type with a limited component; 6/2
- {AI05-0178-1} an incomplete view; 6.1/3
- {AI95-00419-01} a derived type whose parent is limited and is not an interface. 6.2/2

**Ramification:** {AI95-00419-01} Limitedness is not inherited from interfaces; it must be explicitly specified when the parent is an interface. 6.a/2

- 6.b/2 **To be honest:** {AI95-00419-01} A derived type can become nonlimited if **limited** does not appear and the derivation takes place in the visible part of a child package, and the parent type is nonlimited as viewed from the private part or body of the child package.
- 6.c/2 **Reason:** {AI95-00419-01} We considered a rule where limitedness was always inherited from the parent for derived types, but in the case of a type whose parent is an interface, this meant that the first interface is treated differently than other interfaces. It also would have forced users to declare dummy nonlimited interfaces just to get the limitedness right. We also considered a syntax like **not limited** to specify nonlimitedness when the parent was limited, but that was unsavory. The rule given is more uniform and simpler to understand.
- 6.d/2 {AI95-00419-01} The rules for interfaces are asymmetrical, but the language is not: if the parent interface is limited, the presence of the word **limited** determines the limitedness, and nonlimited progenitors are illegal by the rules in 3.9.4 if **limited** is present. If the parent interface is nonlimited, the word **limited** is illegal by the rules in 3.4. The net effect is that the order of the interfaces doesn't matter.
- 7 Otherwise, the type is nonlimited.
- 8 [There are no predefined equality operators for a limited type.]
- 8.1/3 {AI05-0052-1} A type is *immutably limited* if it is one of the following:
- 8.2/3 • An explicitly limited record type;
  - 8.3/3 • {AI05-0217-1} A record extension with the reserved word **limited**;
  - 8.4/3 • A nonformal limited private type that is tagged or has at least one access discriminant with a `default_expression`;
- 8.a/3 **Reason:** The full type in both of these cases must necessarily be immutably limited. We need to include private types as much as possible so that we aren't unintentionally discouraging the use of private types.
- 8.5/3 • A task type, a protected type, or a synchronized interface;
  - 8.6/3 • A type derived from an immutably limited type.
- 8.b/3 **Discussion:** An immutably limited type is a type that cannot become nonlimited subsequently in a private part or in a child unit. If a view of the type makes it immutably limited, then no copying (assignment) operations are ever available for objects of the type. This allows other properties; for instance, it is safe for such objects to have access discriminants that have defaults or designate other limited objects.
- 8.c/3 **Ramification:** A nonsynchronized limited interface type is not immutably limited; a type derived from it can be nonlimited.
- 8.7/3 {AI05-0052-1} A descendant of a generic formal limited private type is presumed to be immutably limited except within the body of a generic unit or a body declared within the declarative region of a generic unit, if the formal type is declared within the formal part of the generic unit.
- 8.d/3 **Ramification:** In an instance, a type is descended from the actual type corresponding to the formal, and all rules are rechecked in the specification. Bodies are excepted so that we assume the worst there; the complex wording is required to handle children of generics and unrelated bodies properly.
- NOTES
- 9/3 15 {AI95-00287-01} {AI95-00318-02} {AI05-0067-1} While it is allowed to write initializations of limited objects, such initializations never copy a limited object. The source of such an assignment operation must be an `aggregate` or `function_call`, and such `aggregates` and `function_calls` must be built directly in the target object (see 7.6).
- 9.a/2 **To be honest:** This isn't quite true if the type can become nonlimited (see below); `function_calls` only are required to be build-in-place for “really” limited types.
- Paragraphs 10 through 15 were deleted.*
- 16 As illustrated in 7.3.1, an untagged limited type can become nonlimited under certain circumstances.
- 16.a **Ramification:** Limited private types do not become nonlimited; instead, their full view can be nonlimited, which has a similar effect.
- 16.b It is important to remember that a single nonprivate type can be both limited and nonlimited in different parts of its scope. In other words, “limited” is a property that depends on where you are in the scope of the type. We don't call this a “view property” because there is no particular declaration to declare the nonlimited view.
- 16.c Tagged types never become nonlimited.

## Examples

Example of a package with a limited type:

```

package IO_Package is
 type File_Name is limited private;
 procedure Open (F : in out File_Name);
 procedure Close(F : in out File_Name);
 procedure Read (F : in File_Name; Item : out Integer);
 procedure Write(F : in File_Name; Item : in Integer);
private
 type File_Name is
 limited record
 Internal_Name : Integer := 0;
 end record;
end IO_Package;

package body IO_Package is
 Limit : constant := 200;
 type File_Descriptor is record ... end record;
 Directory : array (1 .. Limit) of File_Descriptor;
 ...
 procedure Open (F : in out File_Name) is ... end;
 procedure Close(F : in out File_Name) is ... end;
 procedure Read (F : in File_Name; Item : out Integer) is ... end;
 procedure Write(F : in File_Name; Item : in Integer) is ... end;
begin
 ...
end IO_Package;

```

## NOTES

17 *Notes on the example:* In the example above, an outside subprogram making use of `IO_Package` may obtain a file name by calling `Open` and later use it in calls to `Read` and `Write`. Thus, outside the package, a file name obtained from `Open` acts as a kind of password; its internal properties (such as containing a numeric value) are not known and no other operations (such as addition or comparison of internal names) can be performed on a file name. Most importantly, clients of the package cannot make copies of objects of type `File_Name`. 21

This example is characteristic of any case where complete control over the operations of a type is desired. Such packages serve a dual purpose. They prevent a user from making use of the internal structure of the type. They also implement the notion of an encapsulated data type where the only operations on the type are those given in the package specification. 22

{AI95-00318-02} The fact that the full view of `File_Name` is explicitly declared **limited** means that parameter passing will always be by reference and function results will always be built directly in the result object (see 6.2 and 6.5). 23/2

*Extensions to Ada 83*

The restrictions in RM83-7.4.4(4), which disallowed **out** parameters of limited types in certain cases, are removed. 23.a

*Wording Changes from Ada 83*

{AI05-0299-1} Since limitedness and privateness are orthogonal in Ada 95 (and to some extent in Ada 83), this is now its own subclause rather than being a subclause of 7.3, “Private Types and Private Extensions”. 23.b/3

*Extensions to Ada 95*

{AI95-00287-01} {AI95-00318-02} Limited types now have an assignment operation, but its use is restricted such that all uses are build-in-place. This is accomplished by restricting uses to **aggregates** and **function\_calls**. **Aggregates** were not allowed to have a limited type in Ada 95, which causes a compatibility issue discussed in 4.3, “Aggregates”. Compatibility issues with return statements for limited **function\_calls** are discussed in 6.5, “Return Statements”. 23.c/2

*Wording Changes from Ada 95*

{AI95-00411-01} {AI95-00419-01} Rewrote the definition of limited to ensure that interfaces are covered, but that limitedness is not inherited from interfaces. Derived types that explicitly include **limited** are now also covered. 23.d/2

*Wording Changes from Ada 2005*

{AI05-0052-1} {AI05-0217-1} **Correction:** Added a definition for immutably limited types, so that the fairly complex definition does not need to be repeated in rules elsewhere in the Standard. 23.e/3

- 23.f/3 {AI05-0067-1} {AI05-0299-1} **Correction:** The built-in-place rules are consolidated in 7.6, and thus they are removed from this subclause.
- 23.g/3 {AI05-0087-1} **Correction:** Fixed an oversight: class-wide types were never defined to be limited, even if their associated specific type is. It is thought that this oversight was never implemented incorrectly by any compiler, thus we have not classified it as an incompatibility.
- 23.h/3 {AI05-0147-1} Allowed conditional\_expressions in limited constructor contexts — we want to treat these as closely to parentheses as possible.
- 23.i/3 {AI05-0178-1} Added wording so that expression functions can return limited entities.
- 23.j/3 {AI05-0178-1} **Correction:** Added incomplete views to the list of reasons for a view of a type to be limited. This is not a change as the definition already was in 3.10.1. But it is much better to have all of the reasons for limitedness together.

## 7.6 Assignment and Finalization

- 1 [ Three kinds of actions are fundamental to the manipulation of objects: initialization, finalization, and assignment. Every object is initialized, either explicitly or by default, after being created (for example, by an object\_declaration or allocator). Every object is finalized before being destroyed (for example, by leaving a subprogram\_body containing an object\_declaration, or by a call to an instance of Unchecked\_Deallocation). An assignment operation is used as part of assignment\_statements, explicit initialization, parameter passing, and other operations.
- 2 Default definitions for these three fundamental operations are provided by the language, but a *controlled* type gives the user additional control over parts of these operations. In particular, the user can define, for a controlled type, an Initialize procedure which is invoked immediately after the normal default initialization of a controlled object, a Finalize procedure which is invoked immediately before finalization of any of the components of a controlled object, and an Adjust procedure which is invoked as the last step of an assignment to a (nonlimited) controlled object.]
- 2.a **Glossary entry:** A controlled type supports user-defined assignment and finalization. Objects are always finalized before being destroyed.
- 2.b/2 **Ramification:** {AI95-00114-01} {AI95-00287-01} Here's the basic idea of initialization, value adjustment, and finalization, whether or not user defined: When an object is created, if it is explicitly assigned an initial value, the object is either built-in-place from an aggregate or function call (in which case neither Adjust nor Initialize is applied), or the assignment copies and adjusts the initial value. Otherwise, Initialize is applied to it (except in the case of an aggregate as a whole). An assignment\_statement finalizes the target before copying in and adjusting the new value. Whenever an object goes away, it is finalized. Calls on Initialize and Adjust happen bottom-up; that is, components first, followed by the containing object. Calls on Finalize happen top-down; that is, first the containing object, and then its components. These ordering rules ensure that any components will be in a well-defined state when Initialize, Adjust, or Finalize is applied to the containing object.

### Static Semantics

- 3 The following language-defined library package exists:

```
4/3 {8652/0020} {AI95-00126-01} {AI05-0212-1} package Ada.Finalization is
 pragma Pure(Finalization);
5/2 {AI95-00161-01} type Controlled is abstract tagged private;
 pragma Preelaborable_Initialization(Controlled);
6/2 {AI95-00348-01} procedure Initialize (Object : in out Controlled) is null;
 procedure Adjust (Object : in out Controlled) is null;
 procedure Finalize (Object : in out Controlled) is null;
7/2 {AI95-00161-01} type Limited_Controlled is abstract tagged limited private;
 pragma Preelaborable_Initialization(Limited_Controlled);
```

```

{AI95-00348-01} procedure Initialize (Object : in out Limited_Controlled) is 8/2
null;
 procedure Finalize (Object : in out Limited_Controlled) is null;
private
 ... -- not specified by the language
end Ada.Finalization;

```

{AI95-00348-01} A controlled type is a descendant of Controlled or Limited\_Controlled. The predefined "=" operator of type Controlled always returns True, [since this operator is incorporated into the implementation of the predefined equality operator of types derived from Controlled, as explained in 4.5.2.] The type Limited\_Controlled is like Controlled, except that it is limited and it lacks the primitive subprogram Adjust. 9/2

**Discussion:** We say “nonlimited controlled type” (rather than just “controlled type”;) when we want to talk about descendants of Controlled only. 9.a

**Reason:** We considered making Adjust and Finalize abstract. However, a reasonable coding convention is e.g. for Finalize to always call the parent's Finalize after doing whatever work is needed for the extension part. (Unlike CLOS, we have no way to do that automatically in Ada 95.) For this to work, Finalize cannot be abstract. In a generic unit, for a generic formal abstract derived type whose ancestor is Controlled or Limited\_Controlled, calling the ancestor's Finalize would be illegal if it were abstract, even though the actual type might have a concrete version. 9.b

Types Controlled and Limited\_Controlled are abstract, even though they have no abstract primitive subprograms. It is not clear that they need to be abstract, but there seems to be no harm in it, and it might make an implementation's life easier to know that there are no objects of these types — in case the implementation wishes to make them “magic” in some way. 9.c

{AI95-00251-01} For Ada 2005, we considered making these types interfaces. That would have the advantage of allowing them to be added to existing trees. But that was rejected both because it would cause massive disruptions to existing implementations, and because it would be very incompatible due to the “no hidden interfaces” rule. The latter rule would prevent a tagged private type from being completed with a derivation from Controlled or Limited\_Controlled — a very common idiom. 9.d/2

{AI95-00360-01} A type is said to *need finalization* if: 9.1/2

- it is a controlled type, a task type or a protected type; or 9.2/2
- {AI05-0092-1} it has a component whose type needs finalization; or 9.3/3
- {AI05-0013-1} it is a class-wide type; or 9.4/3
- {AI05-0026-1} it is a partial view whose full view needs finalization; or 9.5/3
- it is one of a number of language-defined types that are explicitly defined to need finalization. 9.6/2

**Ramification:** The fact that a type needs finalization does not require it to be implemented with a controlled type. It just has to be recognized by the No\_Nested\_Finalization restriction. 9.e/2

This property is defined for the type, not for a particular view. That's necessary as restrictions look in private parts to enforce their restrictions; the point is to eliminate all controlled parts, not just ones that are visible. 9.f/2

#### Dynamic Semantics

{AI95-00373-01} During the elaboration or evaluation of a construct that causes an object to be initialized by default, for every controlled subcomponent of the object that is not assigned an initial value (as defined in 3.3.1), Initialize is called on that subcomponent. Similarly, if the object that is initialized by default as a whole is controlled, Initialize is called on the object. 10/2

{8652/0021} {AI95-00182-01} {AI95-00373-01} For an extension\_aggregate whose ancestor\_part is a subtype\_mark denoting a controlled subtype, the Initialize procedure of the ancestor type is called, unless that Initialize procedure is abstract. 11/2

**Discussion:** Example: 11.a

```

type T1 is new Controlled with
 record
 ... -- some components might have defaults
 end record;

```

11.b

```

11.c type T2 is new Controlled with
 record
 X : T1; -- no default
 Y : T1 := ...; -- default
 end record;

```

```

11.d A : T2;
 B : T2 := ...;

```

11.e As part of the elaboration of A's declaration, A.Y is assigned a value; therefore Initialize is not applied to A.Y. Instead, Adjust is applied to A.Y as part of the assignment operation. Initialize is applied to A.X and to A, since those objects are not assigned an initial value. The assignment to A.Y is not considered an assignment to A.

11.f For the elaboration of B's declaration, Initialize is not called at all. Instead the assignment adjusts B's value; that is, it applies Adjust to B.X, B.Y, and B.

11.f.1/2 {8652/0021} {AI95-00182-01} {AI95-00373-01} The ancestor\_part of an extension\_aggregate,  $\triangleleft$  in aggregates, and the return object of an extended\_return\_statement are handled similarly.

12 Initialize and other initialization operations are done in an arbitrary order, except as follows. Initialize is applied to an object after initialization of its subcomponents, if any [(including both implicit initialization and Initialize calls)]. If an object has a component with an access discriminant constrained by a per-object expression, Initialize is applied to this component after any components that do not have such discriminants. For an object with several components with such a discriminant, Initialize is applied to them in order of their component\_declarations. For an allocator, any task activations follow all calls on Initialize.

12.a **Reason:** The fact that Initialize is done for subcomponents first allows Initialize for a composite object to refer to its subcomponents knowing they have been properly initialized.

12.b The fact that Initialize is done for components with access discriminants after other components allows the Initialize operation for a component with a self-referential access discriminant to assume that other components of the enclosing object have already been properly initialized. For multiple such components, it allows some predictability.

13 When a target object with any controlled parts is assigned a value, [either when created or in a subsequent assignment\_statement,] the *assignment operation* proceeds as follows:

- 14 • The value of the target becomes the assigned value.
- 15 • The value of the target is *adjusted*.

15.a **Ramification:** If any parts of the object are controlled, abort is deferred during the assignment operation.

16/3 {AI05-0067-1} To adjust the value of a composite object, the values of the components of the object are first adjusted in an arbitrary order, and then, if the object is nonlimited controlled, Adjust is called. Adjusting the value of an elementary object has no effect[, nor does adjusting the value of a composite object with no controlled parts.]

16.a/3 **Ramification:** {AI05-0067-1} Adjustment is never actually performed for values of an immutably limited type, since all assignment operations for such types are required to be built-in-place. Even so, we still define adjustment for all types in order that the canonical semantics is well-defined.

16.b/3 **Reason:** {AI05-0005-1} The verbiage in the Initialize rule about access discriminants constrained by per-object expressions is not necessary here, since such types are either limited or do not have defaults, so the discriminant can only be changed by an assignment to an outer object. Such an assignment could happen only before any adjustments or (if part of an outer Adjust) only after any inner (component) adjustments have completed.

17 For an assignment\_statement, [ after the name and expression have been evaluated, and any conversion (including constraint checking) has been done,] an anonymous object is created, and the value is assigned into it; [that is, the assignment operation is applied]. [(Assignment includes value adjustment.)] The target of the assignment\_statement is then finalized. The value of the anonymous object is then assigned into the target of the assignment\_statement. Finally, the anonymous object is finalized. [As explained below, the implementation may eliminate the intermediate anonymous object, so this description subsumes the one given in 5.2, “Assignment Statements”.]

17.a **Reason:** An alternative design for user-defined assignment might involve an Assign operation instead of Adjust:

```

17.b procedure Assign(Target : in out Controlled; Source : in out Controlled);

```

Or perhaps even a syntax like this:

```
procedure ":=" (Target : in out Controlled; Source : in out Controlled);
```

Assign (or ":=") would have the responsibility of doing the copy, as well as whatever else is necessary. This would have the advantage that the Assign operation knows about both the target and the source at the same time — it would be possible to do things like reuse storage belonging to the target, for example, which Adjust cannot do. However, this sort of design would not work in the case of unconstrained discriminated variables, because there is no way to change the discriminants individually. For example:

```
type Mutable(D : Integer := 0) is
 record
 X : Array_Of_Controlled_Things(1..D);
 case D is
 when 17 => Y : Controlled_Thing;
 when others => null;
 end D;
end record;
```

An assignment to an unconstrained variable of type Mutable can cause some of the components of X, and the component Y, to appear and/or disappear. There is no way to write the Assign operation to handle this sort of case.

Forbidding such cases is not an option — it would cause generic contract model violations.

*{AI05-0067-1}* When a function call or **aggregate** is used to initialize an object, the result of the function call or **aggregate** is an anonymous object, which is assigned into the newly-created object. For such an assignment, the anonymous object might be *built in place*, in which case the assignment does not involve any copying. Under certain circumstances, the anonymous object is required to be built in place. In particular:

**Discussion:** *{AI05-0067-1}* We say assignment to built-in-place objects does not involve copying, which matches the intended implementation (see below). Of course, the implementation can do any copying it likes, if it can make such copying semantically invisible (by patching up access values to point to the copy, and so forth).

- If the full type of any part of the object is immutably limited, the anonymous object is built in place.

**Reason:** *{AI05-0067-1}* We talk about the full types being immutably limited, as this is independent of the view of a type (in the same way that it is for determining the technique of parameter passing). That is, privacy is ignored for this purpose.

*{AI05-0005-1}* *{AI05-0067-1}* For function calls, we only require building in place for immutably limited types. These are the types that would have been return-by-reference types in Ada 95. We limited the requirement because we want to minimize disruption to Ada 95 implementations and users.

**To be honest:** *{AI05-0232-1}* This is a dynamic property and is determined by the specific type of the parts of the actual object. In particular, if a part has a class-wide type, the tag of the object might need to be examined in order to determine if build-in-place is required. However, we expect that most Ada implementations will determine this property at compile-time using some assume-the-worst algorithm in order to choose the appropriate method to implement a given call or aggregate. In addition, there is no attribute or other method for a program to determine if a particular object has this property (or not), so there is no value to a more careful description of this rule.

- In the case of an **aggregate**, if the full type of any part of the newly-created object is controlled, the anonymous object is built in place.

**Reason:** *{AI05-0067-1}* This is necessary to prevent elaboration problems with deferred constants of controlled types. Consider:

```
package P is
 type Dyn_String is private;
 Null_String : constant Dyn_String;
 ...
private
 type Dyn_String is new Ada.Finalization.Controlled with ...
 procedure Finalize(X : in out Dyn_String);
 procedure Adjust(X : in out Dyn_String);

 Null_String : constant Dyn_String :=
 (Ada.Finalization.Controlled with ...);
 ...
end P;
```

- 17.m.2/3 When `Null_String` is elaborated, the bodies of `Finalize` and `Adjust` clearly have not been elaborated. Without this rule, this declaration would necessarily raise `Program_Error` (unless the permissions given below are used by the implementation).
- 17.n/3 **Ramification:** An `aggregate` with a controlled part used in the return expression of a `simple_return_statement` has to be built in place in the anonymous return object, as this is similar to an object declaration. (This is a change from Ada 95, but it is not an inconsistency as it only serves to restrict implementation choices.) But this only covers the `aggregate`; a separate anonymous return object can still be used unless it too is required to be built in place.
- 17.o/3 Similarly, an `aggregate` that has a controlled part but is not itself controlled and that is used to initialize an object also has to be built in place. This is also a change from Ada 95, but it is not an inconsistency as it only serves to restrict implementation choices. This avoids problems if a type like `Dyn_String` (in the example above) is used as a component in a type used as a deferred constant in package `P`.
- 17.4/3 • In other cases, it is unspecified whether the anonymous object is built in place.
- 17.p/3 **Reason:** This is left unspecified so the implementation can use any appropriate criteria for determining when to build in place. That includes making the decision on a call-by-call basis. Reasonable programs will not care what decision is made here anyway.
- 17.5/3 `{AI05-0067-1}` Notwithstanding what this International Standard says elsewhere, if an object is built in place:
- 17.6/3 • Upon successful completion of the return statement or `aggregate`, the anonymous object *mutates into* the newly-created object; that is, the anonymous object ceases to exist, and the newly-created object appears in its place.
- 17.7/3 • Finalization is not performed on the anonymous object.
- 17.8/3 • Adjustment is not performed on the newly-created object.
- 17.9/3 • All access values that designate parts of the anonymous object now designate the corresponding parts of the newly-created object.
- 17.10/3 • All renamings of parts of the anonymous object now denote views of the corresponding parts of the newly-created object.
- 17.11/3 • Coextensions of the anonymous object become coextensions of the newly-created object.
- 17.q/3 **To be honest:** This “mutating” does not necessarily happen atomically with respect to abort and other tasks. For example, if a function call is used as the parent part of an `extension_aggregate`, then the tag of the anonymous object (the function result) will be different from the tag of the newly-created object (the parent part of the `extension_aggregate`). In implementation terms, this involves modifying the tag field. If the current task is aborted during this modification, the object might become abnormal. Likewise, if some other task accesses the tag field during this modification, it constitutes improper use of shared variables, and is erroneous.
- 17.r/3 **Implementation Note:** The intended implementation is that the anonymous object is allocated at the same address as the newly-created object. Thus, no run-time action is required to cause all the access values and renamings to point to the right place. They just point to the newly-created object, which is what the return object has magically “mutated into”.
- 17.s/3 There is no requirement that 'Address of the return object is equal to 'Address of the newly-created object, but that will be true in the intended implementation.
- 17.t/3 For a function call, if the size of the newly-created object is known at the call site, the object is allocated there, and the address is implicitly passed to the function; the return object is created at that address. Otherwise, a storage pool is implicitly passed to the function; the size is determined at the point of the return statement, and passed to the `Allocate` procedure. The address returned by the storage pool is returned from the function, and the newly-created object uses that same address. If the return statement is left without returning (via an exception or a `goto`, for example), then `Deallocate` is called. The storage pool might be a dummy pool that represents “allocate on the stack”.
- 17.u/3 The Tag of the newly-created object may be different from that of the result object. Likewise, the master and accessibility level may be different.
- 17.v/3 An alternative implementation model might allow objects to move around to different addresses. In this case, access values and renamings would need to be modified at run time. It seems that this model requires the full power of tracing garbage collection.

## Implementation Permissions

- {AI05-0067-1}* An implementation is allowed to relax the above rules for `assignment_statements` in the following ways: 18/3
- This paragraph was deleted. {AI05-0067-1}* 18.a/3
- Ramification:** *{AI05-0067-1}* The relaxations apply only to nonlimited types, as `assignment_statements` are not allowed for limited types. This is important so that the programmer can count on a stricter semantics for limited controlled types. 18.b/3
- *{AI05-0067-1}* If an object is assigned the value of that same object, the implementation need not do anything. 19/3
 

**Ramification:** In other words, even if an object is controlled and a combination of `Finalize` and `Adjust` on the object might have a net side effect, they need not be performed. 19.a
  - *{AI05-0067-1}* For assignment of a noncontrolled type, the implementation may finalize and assign each component of the variable separately (rather than finalizing the entire variable and assigning the entire new value) unless a discriminant of the variable is changed by the assignment. 20/3
 

**Reason:** For example, in a slice assignment, an anonymous object is not necessary if the slice is copied component-by-component in the right direction, since array types are not controlled (although their components may be). Note that the direction, and even the fact that it's a slice assignment, can in general be determined only at run time. 20.a

**Ramification:** *{AI05-0005-1}* This potentially breaks a single assignment operation into many, and thus abort deferral (see 9.8) needs to last only across an individual component assignment when the component has a controlled part. It is only important that the copy step is not separated (by an abort) from the adjust step, so aborts between component assignments is not harmful. 20.b/3
  - *{AI95-00147-01}* *{AI05-0067-1}* The implementation need not create an anonymous object if the value being assigned is the result of evaluating a `name` denoting an object (the source object) whose storage cannot overlap with the target. If the source object might overlap with the target object, then the implementation can avoid the need for an intermediary anonymous object by exercising one of the above permissions and perform the assignment one component at a time (for an overlapping array assignment), or not at all (for an assignment where the target and the source of the assignment are the same object). 21/3
 

**Ramification:** *{AI05-0005-1}* If the anonymous object is eliminated by this permission, there is no anonymous object to be finalized and thus the `Finalize` call on it is eliminated. 21.a/3

*{AI95-00147-01}* *{AI05-0005-1}* Note that if the anonymous object is eliminated but the new value is not built in place in the target object, that `Adjust` must be called directly on the target object as the last step of the assignment, since some of the subcomponents may be self-referential or otherwise position-dependent. This `Adjust` can be eliminated only by using one of the following permissions. 21.b/3
- {AI95-00147-01}* Furthermore, an implementation is permitted to omit implicit `Initialize`, `Adjust`, and `Finalize` calls and associated assignment operations on an object of a nonlimited controlled type provided that: 22/2
- any omitted `Initialize` call is not a call on a user-defined `Initialize` procedure, and 23/2
 

**To be honest:** This does not apply to any calls to a user-defined `Initialize` routine that happen to occur in an `Adjust` or `Finalize` routine. It is intended that it is never necessary to look inside of an `Adjust` or `Finalize` routine to determine if the call can be omitted. 23.a/2

**Reason:** We don't want to eliminate objects for which the `Initialize` might have side effects (such as locking a resource). 23.b/2
  - any usage of the value of the object after the implicit `Initialize` or `Adjust` call and before any subsequent `Finalize` call on the object does not change the external effect of the program, and 24/2
  - after the omission of such calls and operations, any execution of the program that executes an `Initialize` or `Adjust` call on an object or initializes an object by an `aggregate` will also later execute a `Finalize` call on the object and will always do so prior to assigning a new value to the object, and 25/2

- 26/2 • the assignment operations associated with omitted Adjust calls are also omitted.
- 27/2 This permission applies to Adjust and Finalize calls even if the implicit calls have additional external effects.

27.a/2 **Reason:** The goal of the above permissions is to allow typical dead assignment and dead variable removal algorithms to work for nonlimited controlled types. We require that “pairs” of Initialize/Adjust/Finalize operations are removed. (These aren’t always pairs, which is why we talk about “any execution of the program”.)

*Extensions to Ada 83*

27.b Controlled types and user-defined finalization are new to Ada 95. (Ada 83 had finalization semantics only for masters of tasks.)

*Extensions to Ada 95*

27.c/2 {AI95-00161-01} **Amendment Correction:** Types Controlled and Limited\_Controlled now have Preelaborable\_Initialization, so that objects of types derived from these types can be used in preelaborated packages.

*Wording Changes from Ada 95*

- 27.d/2 {8652/0020} {AI95-00126-01} **Corrigendum:** Clarified that Ada.Finalization is a remote types package.
- 27.e/2 {8652/0021} {AI95-00182-01} **Corrigendum:** Added wording to clarify that the default initialization (whatever it is) of an ancestor part is used.
- 27.f/2 {8652/0022} {AI95-00083-01} **Corrigendum:** Clarified that Adjust is never called on an aggregate used for the initialization of an object or subaggregate, or passed as a parameter.
- 27.g/2 {AI95-00147-01} Additional optimizations are allowed for nonlimited controlled types. These allow traditional dead variable elimination to be applied to such types.
- 27.h/2 {AI95-00318-02} Corrected the build-in-place requirement for controlled aggregates to be consistent with the requirements for limited types.
- 27.i/2 {AI95-00348-01} The operations of types Controlled and Limited\_Controlled are now declared as null procedures (see 6.7) to make the semantics clear (and to provide a good example of what null procedures can be used for).
- 27.j/2 {AI95-00360-01} Types that need finalization are defined; this is used by the No\_Nested\_Finalization restriction (see D.7, “Tasking Restrictions”).
- 27.k/2 {AI95-00373-01} Generalized the description of objects that have Initialize called for them to say that it is done for all objects that are initialized by default. This is needed so that all of the new cases are covered.

*Extensions to Ada 2005*

27.l/3 {AI05-0212-1} Package Ada.Finalization now has Pure categorization, so it can be mentioned for any package. Note that this does not change the preelaborability of objects descended from Controlled and Limited\_Controlled.

*Wording Changes from Ada 2005*

- 27.m/3 {AI05-0013-1} **Correction:** Eliminated coextensions from the “needs finalization” rules, as this cannot be determined in general in the compilation unit that declares the type. (The designated type of the coextension may have been imported as a limited view.) Uses of “needs finalization” need to ensure that coextensions are handled by other means (such as in No\_Nested\_Finalization – see D.7) or that coextensions cannot happen.
- 27.n/3 {AI05-0013-1} **Correction:** Corrected the “needs finalization” rules to include class-wide types, as a future extension can include a part that needs finalization.
- 27.o/3 {AI05-0026-1} **Correction:** Corrected the “needs finalization” rules to clearly say that they ignore privacy.
- 27.p/3 {AI05-0067-1} **Correction:** Changed “built in place” to Dynamic Semantics and centralized the rules here. This eliminates the fiction that built in place is just a combination of a permission and a requirement; it clearly has noticeable semantic effects. This wording change is not intended to change the semantics of any correct Ada program.

## 7.6.1 Completion and Finalization

- 1 [This subclause defines *completion* and *leaving* of the execution of constructs and entities. A *master* is the execution of a construct that includes finalization of local objects after it is complete (and after waiting

for any local tasks — see 9.3), but before leaving. Other constructs and entities are left immediately upon completion. ]

*Dynamic Semantics*

{AI95-00318-02} The execution of a construct or entity is *complete* when the end of that execution has been reached, or when a transfer of control (see 5.1) causes it to be abandoned. Completion due to reaching the end of execution, or due to the transfer of control of an `exit_statement`, `return_statement`, `goto_statement`, or `requeue_statement` or of the selection of a `terminate_alternative` is *normal completion*. Completion is *abnormal* otherwise [— when control is transferred out of a construct due to abort or the raising of an exception]. 2/2

**Discussion:** Don't confuse the run-time concept of completion with the compile-time concept of completion defined in 3.11.1. 2.a

{AI95-00162-01} {AI95-00416-01} After execution of a construct or entity is complete, it is *left*, meaning that execution continues with the next action, as defined for the execution that is taking place. Leaving an execution happens immediately after its completion, except in the case of a *master*: the execution of a body other than a `package_body`; the execution of a `statement`; or the evaluation of an `expression`, `function_call`, or `range` that is not part of an enclosing `expression`, `function_call`, `range`, or `simple_statement` other than a `simple_return_statement`. A master is finalized after it is complete, and before it is left. 3/2

**Reason:** {AI95-00162-01} {AI95-00416-01} Expressions and statements are masters so that objects created by subprogram calls (in aggregates, allocators for anonymous access-to-object types, and so on) are finalized and have their tasks awaited before the expressions or statements are left. Note that expressions like the condition of an `if_statement` are masters, because they are not enclosed by a `simple_statement`. Similarly, a `function_call` which is renamed is a master, as it is not in a `simple_statement`. 3.a/2

{AI95-00416-01} We have to include `function_calls` in the contexts that do not cause masters to occur so that expressions contained in a `function_call` (that is not part of an `expression` or `simple_statement`) do not individually become masters. We certainly do not want the parameter expressions of a `function_call` to be separate masters, as they would then be finalized before the function is called. 3.b/2

**Ramification:** {AI95-00416-01} The fact that a `function_call` is a master does not change the accessibility of the return object denoted by the `function_call`; that depends on the use of the `function_call`. The `function_call` is the master of any short-lived entities (such as aggregates used as parameters of types with task or controlled parts). 3.c/2

For the *finalization* of a master, dependent tasks are first awaited, as explained in 9.3. Then each object whose accessibility level is the same as that of the master is finalized if the object was successfully initialized and still exists. [These actions are performed whether the master is left by reaching the last statement or via a transfer of control.] When a transfer of control causes completion of an execution, each included master is finalized in order, from innermost outward. 4

**Ramification:** As explained in 3.10.2, the set of objects with the same accessibility level as that of the master includes objects declared immediately within the master, objects declared in nested packages, objects created by allocators (if the ultimate ancestor access type is declared in one of those places) and subcomponents of all of these things. If an object was already finalized by `Unchecked_Deallocation`, then it is not finalized again when the master is left. 4.a

Note that any object whose accessibility level is deeper than that of the master would no longer exist; those objects would have been finalized by some inner master. Thus, after leaving a master, the only objects yet to be finalized are those whose accessibility level is less deep than that of the master. 4.b

**To be honest:** Subcomponents of objects due to be finalized are not finalized by the finalization of the master; they are finalized by the finalization of the containing object. 4.c

**Reason:** We need to finalize subcomponents of objects even if the containing object is not going to get finalized because it was not fully initialized. But if the containing object is finalized, we don't want to require repeated finalization of the subcomponents, as might normally be implied by the recursion in finalization of a master and the recursion in finalization of an object. 4.d

**To be honest:** Formally, completion and leaving refer to executions of constructs or entities. However, the standard sometimes (informally) refers to the constructs or entities whose executions are being completed. Thus, for example, “the subprogram call or task is complete” really means “the execution of the subprogram call or task is complete.” 4.e

- 5 For the *finalization* of an object:
- 6/3 • {AI05-0099-1} If the full type of the object is an elementary type, finalization has no effect;
- 6.a/3 **Reason:** {AI05-0099-1} We say “full type” in this and the following bullets as privacy is ignored for the purpose of determining the finalization actions of an object; that is as expected for Dynamic Semantics rules.
- 7/3 • {AI05-0099-1} If the full type of the object is a tagged type, and the tag of the object identifies a controlled type, the Finalize procedure of that controlled type is called;
- 8/3 • {AI05-0099-1} If the full type of the object is a protected type, or if the full type of the object is a tagged type and the tag of the object identifies a protected type, the actions defined in 9.4 are performed;
- 9/3 • {AI95-00416-01} {AI05-0099-1} If the full type of the object is a composite type, then after performing the above actions, if any, every component of the object is finalized in an arbitrary order, except as follows: if the object has a component with an access discriminant constrained by a per-object expression, this component is finalized before any components that do not have such discriminants; for an object with several components with such a discriminant, they are finalized in the reverse of the order of their `component_declarations`;
- 9.a **Reason:** This allows the finalization of a component with an access discriminant to refer to other components of the enclosing object prior to their being finalized.
- 9.b/3 **To be honest:** {AI05-0099-1} The components discussed here are all of the components that the object actually has, not just those components that are statically identified by the type of the object. These can be different if the object has a classwide type.
- 9.1/2 • {AI95-00416-01} If the object has coextensions (see 3.10.2), each coextension is finalized after the object whose access discriminant designates it.
- 9.c/3 **Ramification:** {AI05-0066-1} In the case of an `aggregate` or function call that is used (in its entirety) to directly initialize a part of an object, the coextensions of the result of evaluating the `aggregate` or function call are transferred to become coextensions of the object being initialized and are not finalized until the object being initialized is ultimately finalized, even if an anonymous object is created as part of the operation.
- 10 Immediately before an instance of `Unchecked_Deallocation` reclaims the storage of an object, the object is finalized. [If an instance of `Unchecked_Deallocation` is never applied to an object created by an `allocator`, the object will still exist when the corresponding master completes, and it will be finalized then.]
- 11/3 {AI95-00280-01} {AI05-0051-1} {AI05-0190-1} The finalization of a master performs finalization of objects created by declarations in the master in the reverse order of their creation. After the finalization of a master is complete, the objects finalized as part of its finalization cease to *exist*, as do any types and subtypes defined and created within the master.
- 11.a/3 *This paragraph was deleted.* {AI05-0190-1}
- 11.b/3 *This paragraph was deleted.* {AI05-0190-1}
- 11.c/3 *This paragraph was deleted.* {AI05-0190-1}
- 11.d/3 *This paragraph was deleted.* {AI05-0190-1}
- 11.e **Ramification:** Note that a deferred constant declaration does not create the constant; the full constant declaration creates it. Therefore, the order of finalization depends on where the full constant declaration occurs, not the deferred constant declaration.
- 11.f An imported object is not created by its declaration. It is neither initialized nor finalized.
- 11.g **Implementation Note:** An implementation has to ensure that the storage for an object is not reclaimed when references to the object are still possible (unless, of course, the user explicitly requests reclamation via an instance of `Unchecked_Deallocation`). This implies, in general, that objects cannot be deallocated one by one as they are finalized; a subsequent finalization might reference an object that has been finalized, and that object had better be in its (well-defined) finalized state.
- 11.1/3 {AI05-0190-1} Each nonderived access type *T* has an associated *collection*, which is the set of objects created by `allocators` of *T*, or of types derived from *T*. `Unchecked_Deallocation` removes an object from

its collection. Finalization of a collection consists of finalization of each object in the collection, in an arbitrary order. The collection of an access type is an object implicitly declared at the following place:

- Ramification:** {AI05-0190-1} The place of the implicit declaration determines when allocated objects are finalized. For multiple collections declared at the same place, we do not define the order of their implicit declarations. 11.h/3
- {AI05-0190-1} Finalization of allocated objects is done according to the (ultimate ancestor) allocator type, not according to the storage pool in which they are allocated. Pool finalization might reclaim storage (see 13.11, “Storage Management”), but has nothing (directly) to do with finalization of the pool elements. 11.i/3
- {AI05-0190-1} Note that finalization is done only for objects that still exist; if an instance of Unchecked\_Deallocation has already gotten rid of a given pool element, that pool element will not be finalized when the master is left. 11.j/3
- Reason:** {AI05-0190-1} Note that we talk about the type of the allocator here. There may be access values of a (general) access type pointing at objects created by allocators for some other type; these are not (necessarily) finalized at this point. 11.k/3
- For a named access type, the first freezing point (see 13.14) of the type. 11.2/3
 

**Reason:** {AI05-0190-1} The freezing point of the ultimate ancestor access type is chosen because before that point, pool elements cannot be created, and after that point, access values designating (parts of) the pool elements can be created. This is also the point after which the pool object cannot have been declared. We don't want to finalize the pool elements until after anything finalizing objects that contain access values designating them. Nor do we want to finalize pool elements after finalizing the pool object itself. 11.l/3
  - For the type of an access parameter, the call that contains the allocator. 11.3/3
  - For the type of an access result, within the master of the call (see 3.10.2). 11.4/3
 

**To be honest:** {AI05-0005-1} {AI05-0190-1} We mean at a place within the master consistent with the execution of the call within the master. We don't say that normatively, as it is difficult to explain that when the master of the call need not be the master that immediately includes the call (such as when an anonymous result is converted to a named access type). 11.m/3
  - For any other anonymous access type, the first freezing point of the innermost enclosing declaration. 11.5/3
- {AI95-00256-01} The target of an `assignment_statement` is finalized before copying in the new value, as explained in 7.6. 12/2
- {8652/0021} {AI95-00182-01} {AI95-00162-01} {AI05-0066-1} {AI05-0142-4} {AI05-0269-1} The master of an object is the master enclosing its creation whose accessibility level (see 3.10.2) is equal to that of the object, except in the case of an anonymous object representing the result of an `aggregate` or function call. If such an anonymous object is part of the result of evaluating the actual parameter expression for an explicitly aliased parameter of a function call, the master of the object is the innermost master enclosing the evaluation of the `aggregate` or function call, excluding the `aggregate` or function call itself. Otherwise, the master of such an anonymous object is the innermost master enclosing the evaluation of the `aggregate` or function call, which may be the `aggregate` or function call itself. 13/3
- This paragraph was deleted.* {AI95-00162-01} 13.a/2
- This paragraph was deleted.* 13.b/2
- This paragraph was deleted.* 13.c/2
- Reason:** {AI95-00162-01} This effectively imports all of the special rules for the accessibility level of renames, allocators, and so on, and applies them to determine where objects created in them are finalized. For instance, the master of a rename of a subprogram is that of the renamed subprogram. 13.d/2
- {AI05-0066-1} In 3.10.2 we assign an accessibility level to the result of an `aggregate` or function call that is used to directly initialize a part of an object based on the object being initialized. This is important to ensure that any access discriminants denote objects that live at least as long as the object being initialized. However, if the result of the `aggregate` or function call is not built directly in the target object, but instead is built in an anonymous object that is then assigned to the target, the anonymous object needs to be finalized after the assignment rather than persisting until the target object is finalized (but not its coextensions). (Note that an implementation is never required to create such an anonymous object, and in some cases is required to *not* have such a separate object, but rather to build the result directly in the target.) 13.e/3

- 13.f/3 {AI05-0142-4} The special case for explicitly aliased parameters of functions is needed for the same reason, as access discriminants of the returned object may designate one of these parameters. In that case, we want to lengthen the lifetime of the anonymous objects as long as the possible lifetime of the result.
- 13.g/3 {AI05-0142-4} We don't do a similar change for other kinds of calls, because the extended lifetime of the parameters adds no value, but could constitute a storage leak. For instance, such an anonymous object created by a procedure call in the elaboration part of a package body would have to live until the end of the program, even though it could not be used after the procedure returns (other than via `Unchecked_Access`).
- 13.h/3 **Ramification:** {AI05-0142-4} Note that the lifetime of the master given to anonymous objects in explicitly aliased parameters of functions is not necessarily as long as the lifetime of the master of the object being initialized (if the function call is used to initialize an `allocator`, for instance). In that case, the accessibility check on explicitly aliased parameters will necessarily fail if any such anonymous objects exist. This is necessary to avoid requiring the objects to live as long as the access type or having the implementation complexity of an implicit coextension.
- 13.l/3 {8652/0023} {AI95-00169-01} {AI95-00162-01} {AI05-0066-1} {AI05-0262-1} In the case of an expression that is a master, finalization of any (anonymous) objects occurs after completing evaluation of the expression and all use of the objects, prior to starting the execution of any subsequent construct.

*Bounded (Run-Time) Errors*

- 14.l/1 {8652/0023} {AI95-00169-01} It is a bounded error for a call on `Finalize` or `Adjust` that occurs as part of object finalization or assignment to propagate an exception. The possible consequences depend on what action invoked the `Finalize` or `Adjust` operation:
- 14.a **Ramification:** It is not a bounded error for `Initialize` to propagate an exception. If `Initialize` propagates an exception, then no further calls on `Initialize` are performed, and those components that have already been initialized (either explicitly or by default) are finalized in the usual way.
- 14.a.1/1 {8652/0023} {AI95-00169-01} It also is not a bounded error for an explicit call to `Finalize` or `Adjust` to propagate an exception. We do not want implementations to have to treat explicit calls to these routines specially.
- 15
- For a `Finalize` invoked as part of an `assignment_statement`, `Program_Error` is raised at that point.
- 16./2
- {8652/0024} {AI95-00193-01} {AI95-00256-01} For an `Adjust` invoked as part of assignment operations other than those invoked as part of an `assignment_statement`, other adjustments due to be performed might or might not be performed, and then `Program_Error` is raised. During its propagation, finalization might or might not be applied to objects whose `Adjust` failed. For an `Adjust` invoked as part of an `assignment_statement`, any other adjustments due to be performed are performed, and then `Program_Error` is raised.
- 16.a/2 **Reason:** {8652/0024} {AI95-00193-01} {AI95-00256-01} In the case of assignments that are part of initialization, there is no need to complete all adjustments if one propagates an exception, as the object will immediately be finalized. So long as a subcomponent is not going to be finalized, it need not be adjusted, even if it is initialized as part of an enclosing composite assignment operation for which some adjustments are performed. However, there is no harm in an implementation making additional `Adjust` calls (as long as any additional components that are adjusted are also finalized), so we allow the implementation flexibility here. On the other hand, for an `assignment_statement`, it is important that all adjustments be performed, even if one fails, because all controlled subcomponents are going to be finalized. Other kinds of assignment are more like initialization than `assignment_statements`, so we include them as well in the permission.
- 16.a.1/1 **Ramification:** {8652/0024} {AI95-00193-01} Even if an `Adjust` invoked as part of the initialization of a controlled object propagates an exception, objects whose initialization (including any `Adjust` or `Initialize` calls) successfully completed will be finalized. The permission above only applies to objects whose `Adjust` failed. Objects for which `Adjust` was never even invoked must not be finalized.
- 17
- For a `Finalize` invoked as part of a call on an instance of `Unchecked_Deallocation`, any other finalizations due to be performed are performed, and then `Program_Error` is raised.
- 17.a.1/1 **Discussion:** {8652/0104} {AI95-00179-01} The standard does not specify if storage is recovered in this case. If storage is not recovered (and the object continues to exist), `Finalize` may be called on the object again (when the `allocator's` master is finalized).
- 17.l/3
- *This paragraph was deleted.* {8652/0023} {AI95-00169-01} {AI05-0064-1}

- {8652/0023} {AI95-00169-01} For a Finalize invoked due to reaching the end of the execution of a master, any other finalizations associated with the master are performed, and Program\_Error is raised immediately after leaving the master. 17.2/1

**Discussion:** {AI05-0064-1} This rule covers both ordinary objects created by a declaration, and anonymous objects created as part of evaluating an expression. All contexts that create objects that need finalization are defined to be masters. 17.a/3
- {AI95-00318-02} For a Finalize invoked by the transfer of control of an `exit_statement`, `return statement`, `goto_statement`, or `requeue_statement`, Program\_Error is raised no earlier than after the finalization of the master being finalized when the exception occurred, and no later than the point where normal execution would have continued. Any other finalizations due to be performed up to that point are performed before raising Program\_Error. 18/2

**Ramification:** For example, upon leaving a `block_statement` due to a `goto_statement`, the Program\_Error would be raised at the point of the target statement denoted by the label, or else in some more dynamically nested place, but not so nested as to allow an `exception_handler` that has visibility upon the finalized object to handle it. For example, 18.a

```

procedure Main is
begin
 <<The_Label>>
 Outer_Block_Statement : declare
 X : Some_Controlled_Type;
 begin
 Inner_Block_Statement : declare
 Y : Some_Controlled_Type;
 Z : Some_Controlled_Type;
 begin
 goto The_Label;
 exception
 when Program_Error => ... -- Handler number 1.
 end;
 exception
 when Program_Error => ... -- Handler number 2.
 end;
 exception
 when Program_Error => ... -- Handler number 3.
 end Inner_Block_Statement;
end Main;

```

18.b

The `goto_statement` will first cause Finalize(Y) to be called. Suppose that Finalize(Y) propagates an exception. Program\_Error will be raised after leaving Inner\_Block\_Statement, but before leaving Main. Thus, handler number 1 cannot handle this Program\_Error; it will be handled either by handler number 2 or handler number 3. If it is handled by handler number 2, then Finalize(Z) will be done before executing the handler. If it is handled by handler number 3, then Finalize(Z) and Finalize(X) will both be done before executing the handler. 18.c
- For a Finalize invoked by a transfer of control that is due to raising an exception, any other finalizations due to be performed for the same master are performed; Program\_Error is raised immediately after leaving the master. 19

**Ramification:** If, in the above example, the `goto_statement` were replaced by a `raise_statement`, then the Program\_Error would be handled by handler number 2, and Finalize(Z) would be done before executing the handler. 19.a

**Reason:** We considered treating this case in the same way as the others, but that would render certain `exception_handlers` useless. For example, suppose the only `exception_handler` is one for `others` in the main subprogram. If some deeply nested call raises an exception, causing some Finalize operation to be called, which then raises an exception, then normal execution “would have continued” at the beginning of the `exception_handler`. Raising Program\_Error at that point would cause that handler's code to be skipped. One would need two nested `exception_handlers` to be sure of catching such cases! 19.b

On the other hand, the `exception_handler` for a given master should not be allowed to handle exceptions raised during finalization of that master. 19.c
- For a Finalize invoked by a transfer of control due to an abort or selection of a terminate alternative, the exception is ignored; any other finalizations due to be performed are performed. 20

**Ramification:** This case includes an asynchronous transfer of control. 20.a

**To be honest:** This violates the general principle that it is always possible for a bounded error to raise Program\_Error (see 1.1.5, “Classification of Errors”). 20.b

## Implementation Permissions

- 20.1/3 {AI05-0107-1} If the execution of an allocator propagates an exception, any parts of the allocated object that were successfully initialized may be finalized as part of the finalization of the innermost master enclosing the allocator.
- 20.c/3 **Reason:** This allows deallocating the memory for the allocated object at the innermost master, preventing a storage leak. Otherwise, the object would have to stay around until the finalization of the collection that it belongs to, which could be the entire life of the program if the associated access type is library level.
- 20.2/3 {AI05-0111-3} {AI05-0262-1} The implementation may finalize objects created by allocators for an access type whose storage pool supports subpools (see 13.11.4) as if the objects were created (in an arbitrary order) at the point where the storage pool was elaborated instead of at the first freezing point of the access type.
- 20.d/3 **Ramification:** This allows the finalization of such objects to occur later than they otherwise would, but still as part of the finalization of the same master. Accessibility rules in 13.11.4 ensure that it is the same master (usually that of the environment task).
- 20.e/3 **Implementation Note:** This permission is intended to allow the allocated objects to "belong" to the subpool objects and to allow those objects to be finalized at the time that the storage pool is finalized (if they are not finalized earlier). This is expected to ease implementation, as the objects will only need to belong to the subpool and not also to the collection.
- NOTES
- 21/3 18 {AI05-0299-1} The rules of Clause 10 imply that immediately prior to partition termination, Finalize operations are applied to library-level controlled objects (including those created by allocators of library-level access types, except those already finalized). This occurs after waiting for library-level tasks to terminate.
- 21.a **Discussion:** We considered defining a pragma that would apply to a controlled type that would suppress Finalize operations for library-level objects of the type upon partition termination. This would be useful for types whose finalization actions consist of simply reclaiming global heap storage, when this is already provided automatically by the environment upon program termination.
- 22 19 A constant is only constant between its initialization and finalization. Both initialization and finalization are allowed to change the value of a constant.
- 23 20 Abort is deferred during certain operations related to controlled types, as explained in 9.8. Those rules prevent an abort from causing a controlled object to be left in an ill-defined state.
- 24 21 The Finalize procedure is called upon finalization of a controlled object, even if Finalize was called earlier, either explicitly or as part of an assignment; hence, if a controlled type is visibly controlled (implying that its Finalize primitive is directly callable), or is nonlimited (implying that assignment is allowed), its Finalize procedure should be designed to have no ill effect if it is applied a second time to the same object.
- 24.a **Discussion:** Or equivalently, a Finalize procedure should be "idempotent"; applying it twice to the same object should be equivalent to applying it once.
- 24.b **Reason:** A user-written Finalize procedure should be idempotent since it can be called explicitly by a client (at least if the type is "visibly" controlled). Also, Finalize is used implicitly as part of the assignment\_statement if the type is nonlimited, and an abort is permitted to disrupt an assignment\_statement between finalizing the left-hand side and assigning the new value to it (an abort is not permitted to disrupt an assignment operation between copying in the new value and adjusting it).
- 24.c/2 **Discussion:** {AI95-00287-01} Either Initialize or Adjust, but not both, is applied to (almost) every controlled object when it is created: Initialize is done when no initial value is assigned to the object, whereas Adjust is done as part of assigning the initial value. The one exception is the object initialized by an aggregate (both the anonymous object created for an aggregate, or an object initialized by an aggregate that is built-in-place); Initialize is not applied to the aggregate as a whole, nor is the value of the aggregate or object adjusted.
- 24.d All of the following use the assignment operation, and thus perform value adjustment:
- 24.e
- the assignment\_statement (see 5.2);
- 24.f
- explicit initialization of a stand-alone object (see 3.3.1) or of a pool element (see 4.8);
- 24.g
- default initialization of a component of a stand-alone object or pool element (in this case, the value of each component is assigned, and therefore adjusted, but the value of the object as a whole is not adjusted);
- 24.h/2
- {AI95-00318-02} function return, when the result is not built-in-place (adjustment of the result happens before finalization of the function);
- 24.i
- predefined operators (although the only one that matters is concatenation; see 4.5.3);

- generic formal objects of mode **in** (see 12.4); these are defined in terms of constant declarations; and 24.j
- *{AI95-00287-01}* **aggregates** (see 4.3), when the result is not built-in-place (in this case, the value of each component, and the parent part, for an `extension_aggregate`, is assigned, and therefore adjusted, but the value of the `aggregate` as a whole is not adjusted; neither is `Initialize` called); 24.k/2

The following also use the assignment operation, but adjustment never does anything interesting in these cases: 24.l

- By-copy parameter passing uses the assignment operation (see 6.4.1), but controlled objects are always passed by reference, so the assignment operation never does anything interesting in this case. If we were to allow by-copy parameter passing for controlled objects, we would need to make sure that the actual is finalized before doing the copy back for **[in] out** parameters. The finalization of the parameter itself needs to happen after the copy back (if any), similar to the finalization of an anonymous function return object or `aggregate` object. 24.m
- **For** loops use the assignment operation (see 5.5), but since the type of the loop parameter is never controlled, nothing interesting happens there, either. 24.n
- *{AI95-00318-02}* Objects initialized by function results and **aggregates** that are built-in-place. In this case, the assignment operation is never executed, and no adjustment takes place. While built-in-place is always allowed, it is required for some types — see 7.5 and 7.6 — and that's important since limited types have no `Adjust` to call. 24.n.1/2

*This paragraph was deleted. {AI95-00287-01}* 24.o/2

Finalization of the parts of a protected object are not done as protected actions. It is possible (in pathological cases) to create tasks during finalization that access these parts in parallel with the finalization itself. This is an erroneous use of shared variables. 24.p

**Implementation Note:** One implementation technique for finalization is to chain the controlled objects together on a per-task list. When leaving a master, the list can be walked up to a marked place. The links needed to implement the list can be declared (privately) in types `Controlled` and `Limited_Controlled`, so they will be inherited by all controlled types. 24.q

Another implementation technique, which we refer to as the “PC-map” approach essentially implies inserting exception handlers at various places, and finalizing objects based on where the exception was raised. 24.r

The PC-map approach is for the compiler/linker to create a map of code addresses; when an exception is raised, or abort occurs, the map can be consulted to see where the task was executing, and what finalization needs to be performed. This approach was given in the Ada 83 Rationale as a possible implementation strategy for exception handling — the map is consulted to determine which exception handler applies. 24.s

If the PC-map approach is used, the implementation must take care in the case of arrays. The generated code will generally contain a loop to initialize an array. If an exception is raised part way through the array, the components that have been initialized must be finalized, and the others must not be finalized. 24.t

It is our intention that both of these implementation methods should be possible. 24.u

#### *Wording Changes from Ada 83*

*{AI05-0299-1}* Finalization depends on the concepts of completion and leaving, and on the concept of a master. Therefore, we have moved the definitions of these concepts here, from where they used to be in Clause 9. These concepts also needed to be generalized somewhat. Task waiting is closely related to user-defined finalization; the rules here refer to the task-waiting rules of Clause 9. 24.v/3

#### *Inconsistencies With Ada 95*

*{AI05-0066-1}* **Ada 2012 Correction:** Changed the definition of the master of an anonymous object used to directly initialize an object, so it can be finalized immediately rather than having to hang around as long as the object. In this case, the Ada 2005 definition was inconsistent with Ada 95, and Ada 2012 changes it back. It is unlikely that many compilers implemented the rule as written in Amendment 1, so an inconsistency is unlikely to arise in practice. 24.v.1/3

#### *Wording Changes from Ada 95*

*{8652/0021}* *{AI95-00182-01}* **Corrigendum:** Fixed the wording to say that anonymous objects aren't finalized until the object can't be used anymore. 24.w/2

*{8652/0023}* *{AI95-00169-01}* **Corrigendum:** Added wording to clarify what happens when `Adjust` or `Finalize` raises an exception; some cases had been omitted. 24.x/2

*{8652/0024}* *{AI95-00193-01}* *{AI95-00256-01}* **Corrigendum:** Stated that if `Adjust` raises an exception during initialization, nothing further is required. This is corrected in Ada 2005 to include all kinds of assignment other than `assignment_statements`. 24.y/2

- 24.z/2      {A195-00162-01} {A195-00416-01} Revised the definition of master to include expressions and statements, in order to cleanly define what happens for tasks and controlled objects created as part of a subprogram call. Having done that, all of the special wording to cover those cases is eliminated (at least until the Ada comments start rolling in).
- 24.aa/2      {A195-00280-01} We define *finalization of the collection* here, so as to be able to conveniently refer to it in other rules (especially in 4.8, “Allocators”).
- 24.bb/2      {A195-00416-01} Clarified that a coextension is finalized at the same time as the outer object. (This was intended for Ada 95, but since the concept did not have a name, it was overlooked.)

*Inconsistencies With Ada 2005*

- 24.cc/3      {A105-0051-1} {A105-0190-1} **Correction:** Better defined when objects allocated from anonymous access types are finalized. This could be inconsistent if objects are finalized in a different order than in an Ada 2005 implementation and that order caused different program behavior; however programs that depend on the order of finalization within a single master are already fragile and hopefully are rare.

*Wording Changes from Ada 2005*

- 24.dd/3      {A105-0064-1} **Correction:** Removed a redundant rule, which is now covered by the additional places where masters are defined.
- 24.ee/3      {A105-0099-1} **Correction:** Clarified the finalization rules so that there is no doubt that privacy is ignored, and to ensure that objects of classwide interface types are finalized based on their specific concrete type.
- 24.ff/3      {A105-0107-1} **Correction:** Allowed premature finalization of parts of failed allocators. This could be an inconsistency, but the previous behavior is still allowed and there is no requirement that implementations take advantage of the permission.
- 24.gg/3      {A105-0111-3} Added a permission to finalize object allocated from a subpool later than usual.
- 24.hh/3      {A105-0142-4} Added text to specially define the master of anonymous objects which are passed as explicitly aliased parameters (see 6.1) of functions. The model for these parameters is explained in detail in 6.4.1.

## 8 Visibility Rules

{AI05-0299-1} [The rules defining the scope of declarations and the rules defining which identifiers, character\_literals, and operator\_symbols are visible at (or from) various places in the text of the program are described in this clause. The formulation of these rules uses the notion of a declarative region. 1/3

{AI05-0299-1} As explained in Clause 3, a declaration declares a view of an entity and associates a defining name with that view. The view comprises an identification of the viewed entity, and possibly additional properties. A usage name denotes a declaration. It also denotes the view declared by that declaration, and denotes the entity of that view. Thus, two different usage names might denote two different views of the same entity; in this case they denote the same entity.] 2/3

**To be honest:** In some cases, a usage name that denotes a declaration does not denote the view declared by that declaration, nor the entity of that view, but instead denotes a view of the current instance of the entity, and denotes the current instance of the entity. This sometimes happens when the usage name occurs inside the declarative region of the declaration. 2.a

### *Wording Changes from Ada 83*

We no longer define the term “basic operation;” thus we no longer have to worry about the visibility of them. Since they were essentially always visible in Ada 83, this change has no effect. The reason for this change is that the definition in Ada 83 was confusing, and not quite correct, and we found it difficult to fix. For example, one wonders why an if\_statement was not a basic operation of type Boolean. For another example, one wonders what it meant for a basic operation to be “inherent in” something. Finally, this fixes the problem addressed by AI83-00027/07. 2.b

### 8.1 Declarative Region

#### *Static Semantics*

For each of the following constructs, there is a portion of the program text called its *declarative region*, [within which nested declarations can occur]: 1

- any declaration, other than that of an enumeration type, that is not a completion [of a previous declaration]; 2
- a block\_statement; 3
- a loop\_statement; 4
- {AI05-0255-1} a quantified\_expression; 4.1/3
- {AI95-00318-02} an extended\_return\_statement; 4.2/3
- an accept\_statement; 5
- an exception\_handler. 6

The declarative region includes the text of the construct together with additional text determined [(recursively)], as follows: 7

- If a declaration is included, so is its completion, if any. 8
- If the declaration of a library unit [(including Standard — see 10.1.1)] is included, so are the declarations of any child units [(and their completions, by the previous rule)]. The child declarations occur after the declaration. 9
- If a body\_stub is included, so is the corresponding subunit. 10
- If a type\_declaration is included, then so is a corresponding record\_representation\_clause, if any. 11

**Reason:** This is so that the component\_declarations can be directly visible in the record\_representation\_clause. 11.a

12 The declarative region of a declaration is also called the *declarative region* of any view or entity declared by the declaration.

12.a **Reason:** The constructs that have declarative regions are the constructs that can have declarations nested inside them. Nested declarations are declared in that declarative region. The one exception is for enumeration literals; although they are nested inside an enumeration type declaration, they behave as if they were declared at the same level as the type.

12.b **To be honest:** A declarative region does not include `parent_unit_names`.

12.c **Ramification:** A declarative region does not include `context_clauses`.

13 A declaration occurs *immediately within* a declarative region if this region is the innermost declarative region that encloses the declaration (the *immediately enclosing* declarative region), not counting the declarative region (if any) associated with the declaration itself.

13.a **Discussion:** Don't confuse the declarative region of a declaration with the declarative region in which it immediately occurs.

14 [ A declaration is *local* to a declarative region if the declaration occurs immediately within the declarative region.] [An entity is *local* to a declarative region if the entity is declared by a declaration that is local to the declarative region.]

14.a **Ramification:** "Occurs immediately within" and "local to" are synonyms (when referring to declarations).

14.b Thus, "local to" applies to both declarations and entities, whereas "occurs immediately within" only applies to declarations. We use this term only informally; for cases where precision is required, we use the term "occurs immediately within", since it is less likely to cause confusion.

15 A declaration is *global* to a declarative region if the declaration occurs immediately within another declarative region that encloses the declarative region. An entity is *global* to a declarative region if the entity is declared by a declaration that is global to the declarative region.

#### NOTES

16 1 The children of a parent library unit are inside the parent's declarative region, even though they do not occur inside the parent's declaration or body. This implies that one can use (for example) "P.Q" to refer to a child of P whose defining name is Q, and that after "**use** P;" Q can refer (directly) to that child.

17 2 As explained above and in 10.1.1, "Compilation Units - Library Units", all library units are descendants of Standard, and so are contained in the declarative region of Standard. They are *not* inside the declaration or body of Standard, but they *are* inside its declarative region.

18 3 For a declarative region that comes in multiple parts, the text of the declarative region does not contain any text that might appear between the parts. Thus, when a portion of a declarative region is said to extend from one place to another in the declarative region, the portion does not contain any text that might appear between the parts of the declarative region.

18.a **Discussion:** It is necessary for the things that have a declarative region to include anything that contains declarations (except for enumeration type declarations). This includes any declaration that has a profile (that is, `subprogram_declaration`, `subprogram_body`, `entry_declaration`, `subprogram_renaming_declaration`, `formal_subprogram_declaration`, `access-to-subprogram_type_declaration`), anything that has a `discriminant_part` (that is, various kinds of `type_declaration`), anything that has a `component_list` (that is, `record_type_declaration` and `record_extension_type_declaration`), and finally the declarations of task and protected units and packages.

#### *Wording Changes from Ada 83*

18.b It was necessary to extend Ada 83's definition of declarative region to take the following Ada 95 features into account:

- 18.c • Child library units.
- 18.d • Derived types/type extensions — we need a declarative region for inherited components and also for new components.
- 18.e • All the kinds of types that allow discriminants.
- 18.f • Protected units.
- 18.g • Entries that have bodies instead of accept statements.
- 18.h • The `choice_parameter_specification` of an `exception_handler`.
- 18.i • The formal parameters of `access-to-subprogram` types.
- 18.j • Renamings-as-body.

Discriminated and access-to-subprogram type declarations need a declarative region. Enumeration type declarations cannot have one, because you don't have to say "Color.Red" to refer to the literal Red of Color. For other type declarations, it doesn't really matter whether or not there is an associated declarative region, so for simplicity, we give one to all types except enumeration types. 18.k

We now say that an `accept_statement` has its own declarative region, rather than being part of the declarative region of the `entry_declaration`, so that declarative regions are properly nested regions of text, so that it makes sense to talk about "inner declarative regions," and "...extends to the end of a declarative region." Inside an `accept_statement`, the name of one of the parameters denotes the `parameter_specification` of the `accept_statement`, not that of the `entry_declaration`. If the `accept_statement` is nested within a `block_statement`, these `parameter_specifications` can hide declarations of the `block_statement`. The semantics of such cases was unclear in RM83. 18.l

**To be honest:** Unfortunately, we have the same problem for the entry name itself — it should denote the `accept_statement`, but `accept_statements` are not declarations. They should be, and they should hide the entry from all visibility within themselves. 18.m

Note that we can't generalize this to `entry_bodies`, or other bodies, because the `declarative_part` of a body is not supposed to contain (explicit) homographs of things in the declaration. It works for `accept_statements` only because an `accept_statement` does not have a `declarative_part`. 18.n

To avoid confusion, we use the term "local to" only informally in Ada 95. Even RM83 used the term incorrectly (see, for example, RM83-12.3(13)). 18.o

In Ada 83, (root) library units were inside Standard; it was not clear whether the declaration or body of Standard was meant. In Ada 95, they are children of Standard, and so occur immediately within Standard's declarative region, but not within either the declaration or the body. (See RM83-8.6(2) and RM83-10.1.1(5).) 18.p

#### *Wording Changes from Ada 95*

{AI95-00318-02} `Extended_return_statement` (see 6.5) is added to the list of constructs that have a declarative region. 18.q/2

## 8.2 Scope of Declarations

[For each declaration, the language rules define a certain portion of the program text called the *scope* of the declaration. The scope of a declaration is also called the scope of any view or entity declared by the declaration. Within the scope of an entity, and only there, there are places where it is legal to refer to the declared entity. These places are defined by the rules of visibility and overloading.] 1

#### *Static Semantics*

The *immediate scope* of a declaration is a portion of the declarative region immediately enclosing the declaration. The immediate scope starts at the beginning of the declaration, except in the case of an overloadable declaration, in which case the immediate scope starts just after the place where the profile of the callable entity is determined (which is at the end of the `_specification` for the callable entity, or at the end of the `generic_instantiation` if an instance). The immediate scope extends to the end of the declarative region, with the following exceptions: 2

**Reason:** The reason for making overloadable declarations with profiles special is to simplify compilation: until the compiler has determined the profile, it doesn't know which other declarations are homographs of this one, so it doesn't know which ones this one should hide. Without this rule, two passes over the `_specification` or `generic_instantiation` would be required to resolve names that denote things with the same name as this one. 2.a

- The immediate scope of a `library_item` includes only its semantic dependents. 3

**Reason:** {AI05-0299-1} Clause 10 defines only a partial ordering of `library_items`. Therefore, it is a good idea to restrict the immediate scope (and the scope, defined below) to semantic dependents. 3.a/3

Consider also examples like this: 3.b

```
package P is end P; 3.c
package P.Q is 3.d
 I : Integer := 0;
end P.Q;
```

- 3.e/1
- ```

with P;
package R is
  package X renames P;
  J : Integer := X.Q.I; -- Illegal!
end R;

```
- 3.f The scope of P.Q does not contain R. Hence, neither P.Q nor X.Q are visible within R. However, the name R.X.Q would be visible in some other library unit where both R and P.Q are visible (assuming R were made legal by removing the offending declaration).
- 3.g/2 **Ramification:** {A195-00217-06} This rule applies to limited views as well as “normal” library items. In that case, the semantic dependents are the units that have a `limited_with_clause` for the limited view.
- 4
- The immediate scope of a declaration in the private part of a library unit does not include the visible part of any public descendant of that library unit.
- 4.a **Ramification:** In other words, a declaration in the private part can be visible within the visible part, private part and body of a private child unit. On the other hand, such a declaration can be visible within only the private part and body of a public child unit.
- 4.b **Reason:** The purpose of this rule is to prevent children from giving private information to clients.
- 4.c/2 **Ramification:** {A195-00231-01} For a public child subprogram, this means that the parent's private part is not visible in the profile of the declaration and of the body. This is true even for `subprogram_bodies` that are not completions. For a public child generic unit, it means that the parent's private part is not visible in the `generic_formal_part`, as well as in the first list of `basic_declarative_items` (for a generic package), or the (syntactic) profile (for a generic subprogram).
- 5 [The *visible part* of (a view of) an entity is a portion of the text of its declaration containing declarations that are visible from outside.] The *private part* of (a view of) an entity that has a visible part contains all declarations within the declaration of (the view of) the entity, except those in the visible part; [these are not visible from outside. Visible and private parts are defined only for these kinds of entities: callable entities, other program units, and composite types.]
- 6
- The visible part of a view of a callable entity is its profile.
- 7
- The visible part of a composite type other than a task or protected type consists of the declarations of all components declared [(explicitly or implicitly)] within the `type_declaration`.
- 8
- The visible part of a generic unit includes the `generic_formal_part`. For a generic package, it also includes the first list of `basic_declarative_items` of the `package_specification`. For a generic subprogram, it also includes the profile.
- 8.a **Reason:** Although there is no way to reference anything but the formals from outside a generic unit, they are still in the visible part in the sense that the corresponding declarations in an instance can be referenced (at least in some cases). In other words, these declarations have an effect on the outside world. The visible part of a generic unit needs to be defined this way in order to properly support the rule that makes a parent's private part invisible within a public child's visible part.
- 8.b **Ramification:** The visible part of an instance of a generic unit is as defined for packages and subprograms; it is not defined in terms of the visible part of a generic unit.
- 9
- [The visible part of a package, task unit, or protected unit consists of declarations in the program unit's declaration other than those following the reserved word **private**, if any; see 7.1 and 12.7 for packages, 9.1 for task units, and 9.4 for protected units.]
- 10 The scope of a declaration always contains the immediate scope of the declaration. In addition, for a given declaration that occurs immediately within the visible part of an outer declaration, or is a public child of an outer declaration, the scope of the given declaration extends to the end of the scope of the outer declaration, except that the scope of a `library_item` includes only its semantic dependents.
- 10.a **Ramification:** Note the recursion. If a declaration appears in the visible part of a library unit, its scope extends to the end of the scope of the library unit, but since that only includes dependents of the declaration of the library unit, the scope of the inner declaration also only includes those dependents. If X renames library package P, which has a child Q, a `with_clause` mentioning P.Q is necessary to be able to refer to X.Q, even if P.Q is visible at the place where X is declared.

{AI95-00408-01} {AI05-0183-1} The scope of an `attribute_definition_clause` is identical to the scope of a declaration that would occur at the point of the `attribute_definition_clause`. The scope of an `aspect_specification` is identical to the scope of the associated declaration. 10.1/3

The immediate scope of a declaration is also the immediate scope of the entity or view declared by the declaration. Similarly, the scope of a declaration is also the scope of the entity or view declared by the declaration. 11

Ramification: The rule for immediate scope implies the following: 11.a

- If the declaration is that of a library unit, then the immediate scope includes the declarative region of the declaration itself, but not other places, unless they are within the scope of a `with_clause` that mentions the library unit. 11.b

It is necessary to attach the semantics of `with_clauses` to [immediate] scopes (as opposed to visibility), in order for various rules to work properly. A library unit should hide a homographic implicit declaration that appears in its parent, but only within the scope of a `with_clause` that mentions the library unit. Otherwise, we would violate the "legality determinable via semantic dependences" rule of 10, "Program Structure and Compilation Issues". The declaration of a library unit should be allowed to be a homograph of an explicit declaration in its parent's body, so long as that body does not mention the library unit in a `with_clause`. 11.c

This means that one cannot denote the declaration of the library unit, but one might still be able to denote the library unit via another view. 11.d

A `with_clause` does not make the declaration of a library unit visible; the lack of a `with_clause` prevents it from being visible. Even if a library unit is mentioned in a `with_clause`, its declaration can still be hidden. 11.e

- The completion of the declaration of a library unit (assuming that's also a declaration) is not visible, neither directly nor by selection, outside that completion. 11.f
- The immediate scope of a declaration immediately within the body of a library unit does not include any child of that library unit. 11.g

This is needed to prevent children from looking inside their parent's body. The children are in the declarative region of the parent, and they might be after the parent's body. Therefore, the scope of a declaration that occurs immediately within the body might include some children. 11.h

NOTES

4 {AI05-0299-1} There are notations for denoting visible declarations that are not directly visible. For example, `parameter_specifications` are in the visible part of a `subprogram_declaration` so that they can be used in named-notation calls appearing outside the called subprogram. For another example, declarations of the visible part of a package can be denoted by expanded names appearing outside the package, and can be made directly visible by a `use_clause`. 12/3

Ramification: {AI95-00114-01} {AI05-0299-1} There are some obscure cases involving generics in which there is no such notation. See Clause 12. 12.a/3

Extensions to Ada 83

The fact that the immediate scope of an overloadable declaration does not include its profile is new to Ada 95. It replaces RM83-8.3(16), which said that within a subprogram specification and within the formal part of an entry declaration or accept statement, all declarations with the same designator as the subprogram or entry were hidden from all visibility. The RM83-8.3(16) rule seemed to be overkill, and created both implementation difficulties and unnecessary semantic complexity. 12.b

Wording Changes from Ada 83

We no longer need to talk about the scope of notations, identifiers, `character_literals`, and `operator_symbols`. 12.c

{AI05-0299-1} The notion of "visible part" has been extended in Ada 95. The syntax of task and protected units now allows private parts, thus requiring us to be able to talk about the visible part as well. It was necessary to extend the concept to subprograms and to generic units, in order for the visibility rules related to child library units to work properly. It was necessary to define the concept separately for generic formal packages, since their visible part is slightly different from that of a normal package. Extending the concept to composite types made the definition of scope slightly simpler. We define visible part for some things elsewhere, since it makes a big difference to the user for those things. For composite types and subprograms, however, the concept is used only in arcane visibility rules, so we localize it to this subclass. 12.d/3

In Ada 83, the semantics of `with_clauses` was described in terms of visibility. It is now described in terms of [immediate] scope. 12.e

We have clarified that the following is illegal (where Q and R are library units): 12.f

- 12.g `package Q is`
 `I : Integer := 0;`
 `end Q;`
- 12.h `package R is`
 `package X renames Standard;`
 `X.Q.I := 17; -- Illegal!`
 `end R;`
- 12.i even though Q is declared in the declarative region of Standard, because R does not mention Q in a `with_clause`.

Wording Changes from Ada 95

- 12.j/2 {AI95-00408-01} The scope of an `attribute_definition_clause` is defined so that it can be used to define the visibility of such a clause, so *that* can be used by the stream attribute availability rules (see 13.13.2).

Wording Changes from Ada 2005

- 12.k/3 {AI05-0183-1} The scope of an `aspect_specification` is defined for similar reasons that it was defined for `attribute_definition_clauses`.

8.3 Visibility

- 1 [The *visibility rules*, given below, determine which declarations are visible and directly visible at each place within a program. The visibility rules apply to both explicit and implicit declarations.]

Static Semantics

- 2 A declaration is defined to be *directly visible* at places where a name consisting of only an identifier or operator_symbol is sufficient to denote the declaration; that is, no `selected_component` notation or special context (such as preceding `=>` in a named association) is necessary to denote the declaration. A declaration is defined to be *visible* wherever it is directly visible, as well as at other places where some name (such as a `selected_component`) can denote the declaration.
- 3 The syntactic category `direct_name` is used to indicate contexts where direct visibility is required. The syntactic category `selector_name` is used to indicate contexts where visibility, but not direct visibility, is required.
- 4 There are two kinds of direct visibility: *immediate visibility* and *use-visibility*. A declaration is immediately visible at a place if it is directly visible because the place is within its immediate scope. A declaration is use-visible if it is directly visible because of a `use_clause` (see 8.4). Both conditions can apply.
- 5 A declaration can be *hidden*, either from direct visibility, or from all visibility, within certain parts of its scope. Where *hidden from all visibility*, it is not visible at all (neither using a `direct_name` nor a `selector_name`). Where *hidden from direct visibility*, only direct visibility is lost; visibility using a `selector_name` is still possible.
- 6 [Two or more declarations are *overloaded* if they all have the same defining name and there is a place where they are all directly visible.]
- 6.a **Ramification:** Note that a name can have more than one possible interpretation even if it denotes a nonoverloadable entity. For example, if there are two functions F that return records, both containing a component called C, then the name F.C has two possible interpretations, even though component declarations are not overloadable.
- 7 The declarations of callable entities [(including enumeration literals)] are *overloadable*[, meaning that overloading is allowed for them].
- 7.a **Ramification:** A `generic_declaration` is not overloadable within its own `generic_formal_part`. This follows from the rules about when a name denotes a current instance. See AI83-00286. This implies that within a `generic_formal_part`, outer declarations with the same defining name are hidden from direct visibility. It also implies that if a generic formal parameter has the same defining name as the generic itself, the formal parameter hides the generic from direct visibility.

Two declarations are <i>homographs</i> if they have the same defining name, and, if both are overloadable, their profiles are type conformant. [An inner declaration hides any outer homograph from direct visibility.]	8
Glossary entry: An overriding operation is one that replaces an inherited primitive operation. Operations may be marked explicitly as overriding or not overriding.	8.a/2
{8652/0025} {AI95-00044-01} [Two homographs are not generally allowed immediately within the same declarative region unless one <i>overrides</i> the other (see Legality Rules below).] The only declarations that are <i>overridable</i> are the implicit declarations for predefined operators and inherited primitive subprograms. A declaration overrides another homograph that occurs immediately within the same declarative region in the following cases:	9/1
<ul style="list-style-type: none"> {8652/0025} {AI95-00044-01} A declaration that is not overridable overrides one that is overridable, [regardless of which declaration occurs first]; 	10/1
<p>Ramification: {8652/0025} {AI95-00044-01} And regardless of whether the nonoverridable declaration is overloadable or not. For example, <code>statement_identifiers</code> are covered by this rule.</p> <p>The “regardless of which declaration occurs first” is there because the explicit declaration could be a primitive subprogram of a partial view, and then the full view might inherit a homograph. We are saying that the explicit one wins (within its scope), even though the implicit one comes later.</p> <p>If the overriding declaration is also a subprogram, then it is a primitive subprogram.</p> <p>As explained in 7.3.1, “Private Operations”, some inherited primitive subprograms are never declared. Such subprograms cannot be overridden, although they can be reached by dispatching calls in the case of a tagged type.</p>	10.a/1 10.b 10.c 10.d
<ul style="list-style-type: none"> The implicit declaration of an inherited operator overrides that of a predefined operator; 	11
<p>Ramification: In a previous version of Ada 9X, we tried to avoid the notion of predefined operators, and say that they were inherited from some magical root type. However, this seemed like too much mechanism. Therefore, a type can have a predefined "+" as well as an inherited "+". The above rule says the inherited one wins.</p> <p>{AI95-00114-01} The “regardless of which declaration occurs first” applies here as well, in the case where <code>derived_type_definition</code> in the visible part of a public library unit derives from a private type declared in the parent unit, and the full view of the parent type has additional predefined operators, as explained in 7.3.1, “Private Operations”. Those predefined operators can be overridden by inherited subprograms implicitly declared earlier.</p>	11.a 11.b/2
<ul style="list-style-type: none"> An implicit declaration of an inherited subprogram overrides a previous implicit declaration of an inherited subprogram. 	12
<ul style="list-style-type: none"> {AI95-00251-01} If two or more homographs are implicitly declared at the same place: <ul style="list-style-type: none"> {AI95-00251-01} If at least one is a subprogram that is neither a null procedure nor an abstract subprogram, and does not require overriding (see 3.9.3), then they override those that are null procedures, abstract subprograms, or require overriding. If more than one such homograph remains that is not thus overridden, then they are all hidden from all visibility. {AI95-00251-01} Otherwise (all are null procedures, abstract subprograms, or require overriding), then any null procedure overrides all abstract subprograms and all subprograms that require overriding; if more than one such homograph remains that is not thus overridden, then if they are all fully conformant with one another, one is chosen arbitrarily; if not, they are all hidden from all visibility. 	12.1/2 12.2/2 12.3/2
<p>Discussion: In the case where the implementation arbitrarily chooses one overrider from among a group of inherited subprograms, users should not be able to determine which member was chosen, as the set of inherited subprograms which are chosen from must be fully conformant. This rule is needed in order to allow</p>	12.a/2
<pre> package Outer is package P1 is type Ifc1 is interface; procedure Null_Procedure (X : Ifc1) is null; procedure Abstract_Subp (X : Ifc1) is abstract; end P1; </pre>	12.b/2

```

12.c/2      package P2 is
              type Ifc2 is interface;
              procedure Null_Procedure (X : Ifc2) is null;
              procedure Abstract_Subp (X : Ifc2) is abstract;
              end P2;
12.d/2      type T is abstract new P1.If1 and P2.If2 with null record;
              end Outer;

```

12.e/2 without requiring that T explicitly override any of its inherited operations.

12.f/2 Full conformance is required here, as we cannot allow the parameter names to differ. If they did differ, the routine which was selected for overriding could be determined by using named parameter notation in a call.

12.g/2 When the subprograms do not conform, we chose not to adopt the “use clause” rule which would make them all visible resulting in likely ambiguity. If we had used such a rule, any successful calls would be confusing; and the fact that there are no Beaujolais-like effect to worry about means we can consider other rules. The hidden-from-all-visibility homographs are still inherited by further derivations, which avoids order-of-declaration dependencies and other anomalies.

12.h/2 We have to be careful to not include arbitrary selection if the routines have real bodies. (This can happen in generics, see the example in the incompatibilities section below.) We don't want the ability to successfully call routines where the body executed depends on the compiler or a phase of the moon.

12.i/2 Note that if the type is concrete, abstract subprograms are inherited as subprograms that require overriding. We include functions that require overriding as well; these don't have real bodies, so they can use the more liberal rules.

- 13
- [For an implicit declaration of a primitive subprogram in a generic unit, there is a copy of this declaration in an instance.] However, a whole new set of primitive subprograms is implicitly declared for each type declared within the visible part of the instance. These new declarations occur immediately after the type declaration, and override the copied ones. [The copied ones can be called only from within the instance; the new ones can be called only from outside the instance, although for tagged types, the body of a new one can be executed by a call to an old one.]

13.a **Discussion:** In addition, this is also stated redundantly (again), and is repeated, in 12.3, “Generic Instantiation”. The rationale for the rule is explained there.

13.b/3 **To be honest:** *{AI05-0042-1}* The implicit subprograms declared when an operation of a progenitor is implemented by an entry or subprogram also override the appropriate implicitly declared inherited operations of the progenitor.

14 A declaration is visible within its scope, except where hidden from all visibility, as follows:

- 15
- An overridden declaration is hidden from all visibility within the scope of the overriding declaration.

15.a **Ramification:** We have to talk about the scope of the overriding declaration, not its visibility, because it hides even when it is itself hidden.

15.b Note that the scope of an explicit `subprogram_declaration` does not start until after its profile.

- 16
- A declaration is hidden from all visibility until the end of the declaration, except:

- 17
- For a record type or record extension, the declaration is hidden from all visibility only until the reserved word **record**;

18/3

- *{AI95-00345-01}* *{AI05-0177-1}* For a `package_declaration`, `generic_package_declaration`, `subprogram_body`, or `expression_function_declaration`, the declaration is hidden from all visibility only until the reserved word **is** of the declaration;

18.a **Ramification:** We're talking about the **is** of the construct itself, here, not some random **is** that might appear in a `generic_formal_part`.

- 18.1/2
- *{AI95-00345-01}* For a task declaration or protected declaration, the declaration is hidden from all visibility only until the reserved word **with** of the declaration if there is one, or the reserved word **is** of the declaration if there is no **with**.

18.b/2 **To be honest:** If there is neither a **with** nor **is**, then the exception does not apply and the name is hidden from all visibility until the end of the declaration. This oddity was inherited from Ada 95.

18.c/2 **Reason:** We need the “**with** or **is**” rule so that the visibility within an `interface_list` does not vary by construct. That would make it harder to complete private extensions and would complicate implementations.

- If the completion of a declaration is a declaration, then within the scope of the completion, the first declaration is hidden from all visibility. Similarly, a `discriminant_specification` or `parameter_specification` is hidden within the scope of a corresponding `discriminant_specification` or `parameter_specification` of a corresponding completion, or of a corresponding `accept_statement`. 19
 - Ramification:** This rule means, for example, that within the scope of a `full_type_declaration` that completes a `private_type_declaration`, the name of the type will denote the `full_type_declaration`, and therefore the full view of the type. On the other hand, if the completion is not a declaration, then it doesn't hide anything, and you can't denote it. 19.a
 - `{AI95-00217-06}` `{AI95-00412-01}` The declaration of a library unit (including a `library_unit_renaming_declaration`) is hidden from all visibility at places outside its declarative region that are not within the scope of a `nonlimited_with_clause` that mentions it. The limited view of a library package is hidden from all visibility at places that are not within the scope of a `limited_with_clause` that mentions it; in addition, the limited view is hidden from all visibility within the declarative region of the package, as well as within the scope of any `nonlimited_with_clause` that mentions the package. Where the declaration of the limited view of a package is visible, any name that denotes the package denotes the limited view, including those provided by a package renaming. 20/2
 - Discussion:** `{AI95-00217-06}` This is the rule that prevents `with_clauses` from being transitive; the [immediate] scope includes indirect semantic dependents. This rule also prevents the limited view of a package from being visible in the same place as the full view of the package, which prevents various ripple effects. 20.a/2
 - `{AI95-00217-06}` `{AI95-00412-01}` [For each declaration or renaming of a generic unit as a child of some parent generic package, there is a corresponding declaration nested immediately within each instance of the parent.] Such a nested declaration is hidden from all visibility except at places that are within the scope of a `with_clause` that mentions the child. 20.1/2
- A declaration with a `defining_identifier` or `defining_operator_symbol` is immediately visible [(and hence directly visible)] within its immediate scope except where hidden from direct visibility, as follows: 21
- A declaration is hidden from direct visibility within the immediate scope of a homograph of the declaration, if the homograph occurs within an inner declarative region; 22
 - A declaration is also hidden from direct visibility where hidden from all visibility. 23
- `{AI95-00195-01}` `{AI95-00408-01}` `{AI05-0183-1}` An `attribute_definition_clause` or an `aspect_specification` is *visible* everywhere within its scope. 23.1/3

Name Resolution Rules

A `direct_name` shall resolve to denote a directly visible declaration whose defining name is the same as the `direct_name`. A `selector_name` shall resolve to denote a visible declaration whose defining name is the same as the `selector_name`. 24

Discussion: "The same as" has the obvious meaning here, so for +, the possible interpretations are declarations whose defining name is "+" (an `operator_symbol`). 24.a

These rules on visibility and direct visibility do not apply in a `context_clause`, a `parent_unit_name`, or a `pragma` that appears at the place of a `compilation_unit`. For those contexts, see the rules in 10.1.6, "Environment-Level Visibility Rules". 25

Ramification: Direct visibility is irrelevant for `character_literals`. In terms of overload resolution `character_literals` are similar to other literals, like `null` — see 4.2. For `character_literals`, there is no need to worry about hiding, since there is no way to declare homographs. 25.a

Legality Rules

`{8652/0025}` `{8652/0026}` `{AI95-00044-01}` `{AI95-00150-01}` `{AI95-00377-01}` A nonoverridable declaration is illegal if there is a homograph occurring immediately within the same declarative region that is visible at the place of the declaration, and is not hidden from all visibility by the nonoverridable 26/2

declaration. In addition, a type extension is illegal if somewhere within its immediate scope it has two visible components with the same name. Similarly, the `context_clause` for a compilation unit is illegal if it mentions (in a `with_clause`) some library unit, and there is a homograph of the library unit that is visible at the place of the compilation unit, and the homograph and the mentioned library unit are both declared immediately within the same declarative region. These rules also apply to dispatching operations declared in the visible part of an instance of a generic unit. However, they do not apply to other overloadable declarations in an instance[; such declarations may have type conformant profiles in the instance, so long as the corresponding declarations in the generic were not type conformant].

26.a **Discussion:** Normally, these rules just mean you can't explicitly declare two homographs immediately within the same declarative region. The wording is designed to handle the following special cases:

26.b • If the second declaration completes the first one, the second declaration is legal.

26.c • If the body of a library unit contains an explicit homograph of a child of that same library unit, this is illegal only if the body mentions the child in its `context_clause`, or if some subunit mentions the child. Here's an example:

26.d

```
package P is
end P;
```

26.e

```
package P.Q is
end P.Q;
```

26.f

```
package body P is
  Q : Integer; -- OK; we cannot see package P.Q here.
  procedure Sub is separate;
end P;
```

26.g

```
with P.Q;
separate(P)
procedure Sub is -- Illegal.
begin
  null;
end Sub;
```

26.h If package body P said "`with P.Q;`", then it would be illegal to declare the homograph `Q: Integer`. But it does not, so the body of P is OK. However, the subunit would be able to see both P.Q's, and is therefore illegal.

26.i A previous version of Ada 9X allowed the subunit, and said that references to P.Q would tend to be ambiguous. However, that was a bad idea, because it requires overload resolution to resolve references to directly visible nonoverloadable homographs, which is something compilers have never before been required to do.

26.i.1/1 • {8652/0026} {8652/0102} {AI95-00150-01} {AI95-00157-01} If a type extension contains a component with the same name as a component in an ancestor type, there must be no place where both components are visible. For instance:

26.i.2/1

```
package A is
  type T is tagged private;
  package B is
    type NT is new T with record
      I: Integer; -- Illegal because T.I is visible in the body.
    end record; -- T.I is not visible here.
  end B;
private
  type T is tagged record
    I: Integer; -- Illegal because T.I is visible in the body.
  end record;
end A;
```

26.i.3/2

```
{AI95-00114-01} package body A is
  package body B is
    -- T.I becomes visible here.
  end B;
end A;
```

26.i.4/1

```
package A.C is
  type NT2 is new A.T with record
    I: Integer; -- Illegal because T.I is visible in the private part.
  end record; -- T.I is not visible here.
private
  -- T.I is visible here.
end A.C;
```

```

with A;
package D is
  type NT3 is new A.T with record
    I: Integer; -- Legal because T.I is never visible in this package.
  end record;
end D;

```

```

with D;
package A.E is
  type NT4 is new D.NT3 with null record;
  X : NT4;
  I1 : Integer := X.I;           -- D.NT3.I
  I2 : Integer := D.NT3(X).I;   -- D.NT3.I
  I3 : Integer := A.T(X).I;     -- A.T.I
end A.E;

```

{8652/0102} {AI95-00157-01} D.NT3 can have a component I because the component I of the parent type is never visible. The parent component exists, of course, but is never declared for the type D.NT3. In the child package A.E, the component I of A.T is visible, but that does not change the fact that the A.T.I component was never declared for type D.NT3. Thus, A.E.NT4 does not (visibly) inherit the component I from A.T, while it does inherit the component I from D.NT3. Of course, both components exist, and can be accessed by a type conversion as shown above. This behavior stems from the fact that every characteristic of a type (including components) must be declared somewhere in the innermost declarative region containing the type — if the characteristic is never visible in that declarative region, it is never declared. Therefore, such characteristics do not suddenly become available even if they are in fact visible in some other scope. See 7.3.1 for more on the rules.

- {AI95-00377-01} It is illegal to mention both an explicit child of an instance, and a child of the generic from which the instance was instantiated. This is easier to understand with an example:

```

generic
package G1 is
end G1;

```

```

generic
package G1.G2 is
end G1.G2;

```

```

with G1;
package I1 is new G1;

```

```

package I1.G2 renames ...

```

```

with G1.G2;
with I1.G2;           -- Illegal
package Bad is ...

```

The context clause for Bad is illegal as I1 has an implicit declaration of I1.G2 based on the generic child G1.G2, as well as the mention of the explicit child I1.G2. As in the previous cases, this is illegal only if the context clause makes both children visible; the explicit child can be mentioned as long as the generic child is not (and vice-versa).

Note that we need to be careful which things we make "hidden from all visibility" versus which things we make simply illegal for names to denote. The distinction is subtle. The rules that disallow names denoting components within a type declaration (see 3.7) do not make the components invisible at those places, so that the above rule makes components with the same name illegal. The same is true for the rule that disallows names denoting formal parameters within a formal_part (see 6.1).

Discussion: The part about instances is from AI83-00012. The reason it says “overloadable declarations” is because we don't want it to apply to type extensions that appear in an instance; components are not overloadable.

NOTES

5 Visibility for compilation units follows from the definition of the environment in 10.1.4, except that it is necessary to apply a with_clause to obtain visibility to a library_unit_declaration or library_unit_renaming_declaration.

6 In addition to the visibility rules given above, the meaning of the occurrence of a direct_name or selector_name at a given place in the text can depend on the overloading rules (see 8.6).

7 Not all contexts where an identifier, character_literal, or operator_symbol are allowed require visibility of a corresponding declaration. Contexts where visibility is not required are identified by using one of these three syntactic categories directly in a syntax rule, rather than using direct_name or selector_name.

Ramification: An identifier, character_literal or operator_symbol that occurs in one of the following contexts is not required to denote a visible or directly visible declaration:

1. A defining name.
2. The identifiers or operator_symbol that appear after the reserved word **end** in a proper_body. Similarly for “**end loop**”, etc.

- 29.d 3. An `attribute_designator`.
- 29.e 4. A pragma identifier.
- 29.f 5. A `pragma_argument_identifier`.
- 29.g 6. An identifier specific to a pragma used in a pragma argument.
- 29.g.1/3 7. *{AI05-0183-1}* An `aspect_mark`;
- 29.g.2/3 8. *{AI05-0183-1}* An identifier specific to an aspect used in an `aspect_definition`.
- 29.h The visibility rules have nothing to do with the above cases; the meanings of such things are defined elsewhere. Reserved words are not identifiers; the visibility rules don't apply to them either.
- 29.i Because of the way we have defined "declaration", it is possible for a usage name to denote a `subprogram_body`, either within that body, or (for a nonlibrary unit) after it (since the body hides the corresponding declaration, if any). Other bodies do not work that way. Completions of `type_declarations` and deferred constant declarations do work that way. `Accept_statements` are never denoted, although the `parameter_specifications` in their profiles can be.
- 29.j The scope of a subprogram does not start until after its profile. Thus, the following is legal:
- 29.k

```
X : constant Integer := 17;
...
package P is
  procedure X(Y : in Integer := X);
end P;
```
- 29.l The body of the subprogram will probably be illegal, however, since the constant X will be hidden by then.
- 29.m The rule is different for generic subprograms, since they are not overloadable; the following is illegal:
- 29.n

```
X : constant Integer := 17;
package P is
  generic
    Z : Integer := X; -- Illegal!
  procedure X(Y : in Integer := X); -- Illegal!
end P;
```
- 29.o The constant X is hidden from direct visibility by the generic declaration.
- Extensions to Ada 83*
- 29.p Declarations with the same defining name as that of a subprogram or entry being defined are nevertheless visible within the subprogram specification or entry declaration.
- Wording Changes from Ada 83*
- 29.q The term “visible by selection” is no longer defined. We use the terms “directly visible” and “visible” (among other things). There are only two regions of text that are of interest, here: the region in which a declaration is visible, and the region in which it is directly visible.
- 29.r Visibility is defined only for declarations.
- Incompatibilities With Ada 95*
- 29.s/2 *{AI95-00251-01}* Added rules to handle the inheritance and overriding of multiple homographs for a single type declaration, in order to support multiple inheritance from interfaces. The new rules are intended to be compatible with the existing rules so that programs that do not use interfaces do not change their legality. However, there is a very rare case where this is not true:
- 29.t/2

```
generic
  type T1 is private;
  type T2 is private;
package G is
  type T is null record;
  procedure P (X : T; Y : T1);
  procedure P (X : T; Z : T2);
end G;]
```
- 29.u/2

```
package I is new G (Integer, Integer); -- Exports homographs of P.
```
- 29.v/2

```
type D is new I.T; -- Both Ps are inherited.
```
- 29.w/2

```
Obj : D;
```
- 29.x/2

```
P (Obj, Z => 10); -- Legal in Ada 95, illegal in Ada 2005.
```
- 29.y/2 The call to P would resolve in Ada 95 by using the parameter name, while the procedures P would be hidden from all visibility in Ada 2005 and thus would not resolve. This case doesn't seem worth making the rules any more complex than they already are.

{AI95-00377-01} **Amendment Correction:** A `with_clause` is illegal if it would create a homograph of an implicitly declared generic child (see 10.1.1). An Ada 95 compiler could have allowed this, but which unit of the two units involved would be denoted wasn't specified, so any successful use isn't portable. Removing one of the two `with_clauses` involved will fix the problem. 29.z/2

Wording Changes from Ada 95

{8652/0025} {AI95-00044-01} **Corrigendum:** Clarified the overriding rules so that `"!="` and `statement_identifiers` are covered. 29.aa/2

{8652/0026} {AI95-00150-01} **Corrigendum:** Clarified that it is never possible for two components with the same name to be visible; any such program is illegal. 29.bb/2

{AI95-00195-01} {AI95-00408-01} The visibility of an `attribute_definition_clause` is defined so that it can be used by the stream attribute availability rules (see 13.13.2). 29.cc/2

{AI95-00217-06} The visibility of a limited view of a library package is defined (see 10.1.1). 29.dd/2

Wording Changes from Ada 2005

{AI05-0177-1} Added wording so that the parameters of an `expression_function_declaration` are visible in the expression of the function. (It would be pretty useless without such a rule.) 29.ee/3

{AI05-0183-1} The visibility of an `aspect_specification` is defined so that it can be used in various other rules. 29.ff/3

8.3.1 Overriding Indicators

{AI95-00218-03} An `overriding_indicator` is used to declare that an operation is intended to override (or not override) an inherited operation. 1/2

Syntax

{AI95-00218-03} `overriding_indicator ::= [not] overriding` 2/2

Legality Rules

{AI95-00218-03} {AI95-00348-01} {AI95-00397-01} {AI05-0177-1} If an `abstract_subprogram_declaration`, `null_procedure_declaration`, `expression_function_declaration`, `subprogram_body`, `subprogram_body_stub`, `subprogram_renaming_declaration`, `generic_instantiation` of a subprogram, or `subprogram_declaration` other than a protected subprogram has an `overriding_indicator`, then: 3/3

- the operation shall be a primitive operation for some type; 4/2
- if the `overriding_indicator` is **overriding**, then the operation shall override a homograph at the place of the declaration or body; 5/2

To be honest: {AI05-0005-1} This doesn't require that the overriding happen at precisely the place of the declaration or body; it only requires that the region in which the overriding is known to have happened includes this place. That is, the overriding can happen at or before the place of the declaration or body. 5.a/3

- if the `overriding_indicator` is **not overriding**, then the operation shall not override any homograph (at any place). 6/2

In addition to the places where Legality Rules normally apply, these rules also apply in the private part of an instance of a generic unit. 7/2

Discussion: The **overriding** and **not overriding** rules differ slightly. For **overriding**, we want the indicator to reflect the overriding state at the place of the declaration; otherwise the indicator would be “lying”. Whether a homograph is implicitly declared after the declaration (see 7.3.1 to see how this can happen) has no impact on this check. However, **not overriding** is different; “lying” would happen if a homograph declared later actually is overriding. So, we require this check to take into account later overridings. That can be implemented either by looking ahead, or by rechecking when additional operations are declared. 7.a/2

The “no lying” rules are needed to prevent a `subprogram_declaration` and `subprogram_body` from having contradictory `overriding_indicators`. 7.b/2

NOTES

- 8/2 8 {AI95-00397-01} Rules for overriding_indicators of task and protected entries and of protected subprograms are found in 9.5.2 and 9.4, respectively.

Examples

- 9/2 {AI95-00433-01} The use of overriding_indicators allows the detection of errors at compile-time that otherwise might not be detected at all. For instance, we might declare a security queue derived from the Queue interface of 3.9.4 as:

```

10/2   type Security_Queue is new Queue with record ...;
11/2   overriding
12/2   procedure Append(Q : in out Security_Queue; Person : in Person_Name);
13/2   overriding
14/2   procedure Remove_First(Q : in out Security_Queue; Person : in Person_Name);
15/2   overriding
16/2   function Cur_Count(Q : in Security_Queue) return Natural;
17/2   overriding
18/2   function Max_Count(Q : in Security_Queue) return Natural;
19/2   not overriding
20/2   procedure Arrest(Q : in out Security_Queue; Person : in Person_Name);

```

- 16/2 The first four subprogram declarations guarantee that these subprograms will override the four subprograms inherited from the Queue interface. A misspelling in one of these subprograms will be detected by the implementation. Conversely, the declaration of Arrest guarantees that this is a new operation.

- 16.a/2 **Discussion:** In this case, the subprograms are abstract, so misspellings will get detected anyway. But for other subprograms (especially when deriving from concrete types), the error might never be detected, and a body other than the one the programmer intended might be executed without warning. Thus our new motto: “Overriding indicators — don’t derive a type without them!”

Extensions to Ada 95

- 16.b/2 {AI95-00218-03} Overriding_indicators are new. These let the programmer state her overriding intentions to the compiler; if the compiler disagrees, an error will be produced rather than a hard to find bug.

Wording Changes from Ada 2005

- 16.c/3 {AI95-0177-1} Expression functions can have overriding indicators.

8.4 Use Clauses

- 1 [A use_package_clause achieves direct visibility of declarations that appear in the visible part of a package; a use_type_clause achieves direct visibility of the primitive operators of a type.]

Language Design Principles

- 1.a If and only if the visibility rules allow P.A, "use P;" should make A directly visible (barring name conflicts). This means, for example, that child library units, and generic formals of a formal package whose formal_package_actual_part is (<>), should be made visible by a use_clause for the appropriate package.
- 1.b The rules for use_clauses were carefully constructed to avoid so-called *Beaujolais* effects, where the addition or removal of a single use_clause, or a single declaration in a "use"d package, would change the meaning of a program from one legal interpretation to another.

Syntax

- ```

2 use_clause ::= use_package_clause | use_type_clause
3 use_package_clause ::= use package_name {, package_name};
4/3 {AI05-0150-1} use_type_clause ::= use [all] type subtype_mark {, subtype_mark};

```

## Legality Rules

{AI95-00217-06} A *package\_name* of a *use\_package\_clause* shall denote a nonlimited view of a package. 5/2

**Ramification:** This includes formal packages. 5.a

## Static Semantics

For each *use\_clause*, there is a certain region of text called the *scope* of the *use\_clause*. For a *use\_clause* within a *context\_clause* of a *library\_unit\_declaration* or *library\_unit\_renaming\_declaration*, the scope is the entire declarative region of the declaration. For a *use\_clause* within a *context\_clause* of a body, the scope is the entire body [and any subunits (including multiply nested subunits). The scope does not include *context\_clauses* themselves.] 6

For a *use\_clause* immediately within a declarative region, the scope is the portion of the declarative region starting just after the *use\_clause* and extending to the end of the declarative region. However, the scope of a *use\_clause* in the private part of a library unit does not include the visible part of any public descendant of that library unit. 7

**Reason:** The exception echoes the similar exception for “immediate scope (of a declaration)” (see 8.2). It makes *use\_clauses* work like this: 7.a

```
package P is
 type T is range 1..10;
end P; 7.b
```

```
with P; 7.c
```

```
package Parent is
private
 use P;
 X : T;
end Parent; 7.c
```

```
package Parent.Child is
 Y : T; -- Illegal!
 Z : P.T;
private
 W : T;
end Parent.Child; 7.d
```

The declaration of Y is illegal because the scope of the “*use P*” does not include that place, so T is not directly visible there. The declarations of X, Z, and W are legal. 7.e

{AI95-00217-06} A package is *named* in a *use\_package\_clause* if it is denoted by a *package\_name* of that clause. A type is *named* in a *use\_type\_clause* if it is determined by a *subtype\_mark* of that clause. 7.1/2

{AI95-00217-06} {AI05-0150-1} For each package named in a *use\_package\_clause* whose scope encloses a place, each declaration that occurs immediately within the declarative region of the package is *potentially use-visible* at this place if the declaration is visible at this place. For each type *T* or *TClass* named in a *use\_type\_clause* whose scope encloses a place, the declaration of each primitive operator of type *T* is potentially use-visible at this place if its declaration is visible at this place. If a *use\_type\_clause* whose scope encloses a place includes the reserved word **all**, then the following entities are also potentially use-visible at this place if the declaration of the entity is visible at this place: 8/3

- {AI05-0150-1} Each primitive subprogram of *T* including each enumeration literal (if any); 8.1/3
- {AI05-0150-1} Each subprogram that is declared immediately within the declarative region in which an ancestor type of *T* is declared and that operates on a class-wide type that covers *T*. 8.2/3

**Ramification:** {AI05-0150-1} Primitive subprograms whose defining name is an identifier are *not* made potentially visible by a *use\_type\_clause* unless reserved word **all** is included. A *use\_type\_clause* without **all** is only for operators. 8.a/3

The semantics described here should be similar to the semantics for expanded names given in 4.1.3, “Selected Components” so as to achieve the effect requested by the “principle of equivalence of *use\_clauses* and 8.b

selected\_components.” Thus, child library units and generic formal parameters of a formal package are potentially use-visible when their enclosing package is use'd.

8.c The "visible at that place" part implies that applying a `use_clause` to a parent unit does not make all of its children use-visible — only those that have been made visible by a `with_clause`. It also implies that we don't have to worry about hiding in the definition of "directly visible" — a declaration cannot be use-visible unless it is visible.

8.d Note that "`use type TClass;`" is equivalent to "`use type T;`", which helps avoid breaking the generic contract model.

8.3/3 {AI05-0131-1} Certain implicit declarations may become potentially use-visible in certain contexts as described in 12.6.

9 A declaration is *use-visible* if it is potentially use-visible, except in these naming-conflict cases:

- 10 • A potentially use-visible declaration is not use-visible if the place considered is within the immediate scope of a homograph of the declaration.
- 11 • Potentially use-visible declarations that have the same identifier are not use-visible unless each of them is an overloadable declaration.

11.a **Ramification:** Overloadable declarations don't cancel each other out, even if they are homographs, though if they are not distinguishable by formal parameter names or the presence or absence of `default_expressions`, any use will be ambiguous. We only mention identifiers here, because declarations named by `operator_symbols` are always overloadable, and hence never cancel each other. Direct visibility is irrelevant for `character_literals`.

#### *Dynamic Semantics*

12 The elaboration of a `use_clause` has no effect.

#### *Examples*

13 *Example of a use clause in a context clause:*

14 `with Ada.Calendar; use Ada;`

15 *Example of a use type clause:*

16 `use type Rational_Numbers.Rational; -- see 7.1`  
 16 `Two_Thirds: Rational_Numbers.Rational := 2/3;`

16.a **Ramification:** In "`use X, Y;`", Y cannot refer to something made visible by the "`use`" of X. Thus, it's not (quite) equivalent to "`use X; use Y;`".

16.b If a given declaration is already immediately visible, then a `use_clause` that makes it potentially use-visible has no effect. Therefore, a `use_type_clause` for a type whose declaration appears in a place other than the visible part of a package has no effect; it cannot make a declaration use-visible unless that declaration is already immediately visible.

16.c "`Use type S1;`" and "`use type S2;`" are equivalent if S1 and S2 are both subtypes of the same type. In particular, "`use type S;`" and "`use type S'Base;`" are equivalent.

16.d **Reason:** We considered adding a rule that prevented several declarations of views of the same entity that all have the same semantics from cancelling each other out. For example, if a (possibly implicit) `subprogram_declaration` for "+" is potentially use-visible, and a fully conformant renaming of it is also potentially use-visible, then they (annoyingly) cancel each other out; neither one is use-visible. The considered rule would have made just one of them use-visible. We gave up on this idea due to the complexity of the rule. It would have had to account for both overloadable and nonoverloadable `renaming_declarations`, the case where the rule should apply only to some subset of the declarations with the same defining name, and the case of `subtype_declarations` (since they are claimed to be sufficient for renaming of subtypes).

#### *Extensions to Ada 83*

16.e The `use_type_clause` is new to Ada 95.

#### *Wording Changes from Ada 83*

16.f The phrase "omitting from this set any packages that enclose this place" is no longer necessary to avoid making something visible outside its scope, because we explicitly state that the declaration has to be visible in order to be potentially use-visible.

*Wording Changes from Ada 95*

{AI95-00217-06} Limited views of packages are not allowed in use clauses. Defined *named in a use clause* for use in other limited view rules (see 10.1.2). 16.g/2

*Extensions to Ada 2005*

{AI05-0150-1} The **use all type** version of the `use_type_clause` is new to Ada 2012. It works similarly to prefixed views. 16.h/3

*Wording Changes from Ada 2005*

{AI05-0131-1} **Correction:** Added wording to allow other declarations to be potentially use-visible, to support corrections to formal subprograms. 16.i/3

## 8.5 Renaming Declarations

[A `renaming_declaration` declares another name for an entity, such as an object, exception, package, subprogram, entry, or generic unit. Alternatively, a `subprogram_renaming_declaration` can be the completion of a previous `subprogram_declaration`.] 1

**Glossary entry:** A `renaming_declaration` is a declaration that does not define a new entity, but instead defines a view of an existing entity. 1.a.1/2

*Syntax*

```
renaming_declaration ::=
 object_renaming_declaration
 | exception_renaming_declaration
 | package_renaming_declaration
 | subprogram_renaming_declaration
 | generic_renaming_declaration 2
```

*Dynamic Semantics*

The elaboration of a `renaming_declaration` evaluates the name that follows the reserved word **renames** and thereby determines the view and entity denoted by this name (the *renamed view* and *renamed entity*). [A name that denotes the `renaming_declaration` denotes (a new view of) the renamed entity.] 3

## NOTES

9 Renaming may be used to resolve name conflicts and to act as a shorthand. Renaming with a different identifier or operator\_symbol does not hide the old name; the new name and the old name need not be visible at the same places. 4

10 A task or protected object that is declared by an explicit `object_declaration` can be renamed as an object. However, a single task or protected object cannot be renamed since the corresponding type is anonymous (meaning it has no nameable subtypes). For similar reasons, an object of an anonymous array or access type cannot be renamed. 5

11 A subtype defined without any additional constraint can be used to achieve the effect of renaming another subtype (including a task or protected subtype) as in 6

```
subtype Mode is Ada.Text_IO.File_Mode; 7
```

*Wording Changes from Ada 83*

The second sentence of RM83-8.5(3), “At any point where a renaming declaration is visible, the identifier, or operator symbol of this declaration denotes the renamed entity.” is incorrect. It doesn’t say directly visible. Also, such an identifier might resolve to something else. 7.a

The verbiage about renamings being legal “only if exactly one...”, which appears in RM83-8.5(4) (for objects) and RM83-8.5(7) (for subprograms) is removed, because it follows from the normal rules about overload resolution. For language lawyers, these facts are obvious; for programmers, they are irrelevant, since failing these tests is highly unlikely. 7.b

## 8.5.1 Object Renaming Declarations

1 [An `object_renaming_declaration` is used to rename an object.]

### Syntax

2/3 `{AI95-00230-01} {AI95-00423-01} {AI05-0183-1} object_renaming_declaration ::=`  
     `defining_identifier : [null_exclusion] subtype_mark renames object_name`  
     `[aspect_specification];`  
     `| defining_identifier : access_definition renames object_name`  
     `[aspect_specification];`

### Name Resolution Rules

3/2 `{AI95-00230-01} {AI95-00254-01} {AI95-00409-01}` The type of the `object_name` shall resolve to the type determined by the `subtype_mark`, or in the case where the type is defined by an `access_definition`, to an anonymous access type. If the anonymous access type is an access-to-object type, the type of the `object_name` shall have the same designated type as that of the `access_definition`. If the anonymous access type is an access-to-subprogram type, the type of the `object_name` shall have a designated profile that is type conformant with that of the `access_definition`.

3.a **Reason:** A previous version of Ada 9X used the usual “expected type” wording:  
 “The expected type for the `object_name` is that determined by the `subtype_mark`.”  
 We changed it so that this would be illegal:

3.b `X: T;`  
`Y: T'Class renames X; -- Illegal!`

3.c When the above was legal, it was unclear whether Y was of type T or T'Class. Note that we still allow this:

3.d `Z: T'Class := ...;`  
`W: T renames F(Z);`

3.e where F is a function with a controlling parameter and result. This is admittedly a bit odd.

3.f Note that the matching rule for generic formal parameters of mode **in out** was changed to keep it consistent with the rule for renaming. That makes the rule different for **in** vs. **in out**.

### Legality Rules

4 The renamed entity shall be an object.

4.1/2 `{AI95-00231-01} {AI95-00409-01}` In the case where the type is defined by an `access_definition`, the type of the renamed object and the type defined by the `access_definition`:

4.2/2 • `{AI95-00231-01} {AI95-00409-01}` shall both be access-to-object types with statically matching designated subtypes and with both or neither being access-to-constant types; or

4.3/2 • `{AI95-00409-01}` shall both be access-to-subprogram types with subtype conformant designated profiles.

4.4/2 `{AI95-00423-01}` For an `object_renaming_declaration` with a `null_exclusion` or an `access_definition` that has a `null_exclusion`:

4.5/2 • if the `object_name` denotes a generic formal object of a generic unit *G*, and the `object_renaming_declaration` occurs within the body of *G* or within the body of a generic unit declared within the declarative region of *G*, then the declaration of the formal object of *G* shall have a `null_exclusion`;

4.6/2 • otherwise, the subtype of the `object_name` shall exclude null. In addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit.

4.a/2 **Reason:** This rule prevents “lying”. **Null** must never be the value of an object with an explicit `null_exclusion`. The first bullet is an assume-the-worst rule which prevents trouble in one obscure case:

```

type Acc_I is access Integer;
subtype Acc_NN_I is not null Acc_I;
Obj : Acc_I := null;

generic
 B : in out Acc_NN_I;
package Gen is
 ...
end Gen;

package body Gen is
 D : not null Acc_I renames B;
end Gen;

package Inst is new Gen (B => Obj);

```

Without the first bullet rule, D would be legal, and contain the value **null**, because the rule about lying is satisfied for generic matching (Obj matches B; B does not explicitly state **not null**), Legality Rules are not rechecked in the body of any instance, and the template passes the lying rule as well. The rule is so complex because it has to apply to formals used in bodies of child generics as well as in the bodies of generics.

{8652/0017} {AI95-00184-01} {AI95-00363-01} {AI05-0008-1} The renamed entity shall not be a subcomponent that depends on discriminants of an object whose nominal subtype is unconstrained unless the object is known to be constrained. A slice of an array shall not be renamed if this restriction disallows renaming of the array. In addition to the places where Legality Rules normally apply, these rules apply also in the private part of an instance of a generic unit.

**Reason:** This prevents renaming of subcomponents that might disappear, which might leave dangling references. Similar restrictions exist for the Access attribute. 5.a

{8652/0017} {AI95-00184-01} {AI05-0008-1} The “recheck on instantiation” requirement on generics is necessary to avoid renaming of components which could disappear even when the nominal subtype would prevent the problem: 5.a.1/3

```

type T1 (D1 : Boolean) is
 record
 case D1 is
 when False =>
 C1 : Integer;
 when True =>
 null;
 end case;
 end record;

generic
 type F is new T1;
 X : in out F;
package G is
 C1_Ren : Integer renames X.C1;
end G;

type T2 (D2 : Boolean := False) is new T1 (D1 => D2);

Y : T2;

package I is new G (T2, Y);

```

Y := (D1 => True); -- *Oops! What happened to I.C1\_Ren?*

{AI05-0008-1} In addition, the “known to be constrained” rules include assume-the-worst rules for generic bodies partially to prevent such problems. 5.a.5/3

**Implementation Note:** Note that if an implementation chooses to deallocate-then-reallocate on assignment\_ statements assigning to unconstrained definite objects, then it cannot represent renamings and access values as simple addresses, because the above rule does not apply to all components of such an object. 5.b

**Ramification:** If it is a generic formal object, then the assume-the-best or assume-the-worst rules are applied as appropriate. 5.c

#### Static Semantics

{AI95-00230-01} {AI95-00409-01} An `object_renaming_declaration` declares a new view [of the renamed object] whose properties are identical to those of the renamed view. [Thus, the properties of the renamed object are not affected by the `renaming_declaration`. In particular, its value and whether or not it is a constant are unaffected; similarly, the null exclusion or constraints that apply to an object are not

affected by renaming (any constraint implied by the `subtype_mark` or `access_definition` of the `object_renaming_declaration` is ignored).]

- 6.a **Discussion:** Because the constraints are ignored, it is a good idea to use the nominal subtype of the renamed object when writing an `object_renaming_declaration`.
- 6.b/2 {AI95-00409-01} If no `null_exclusion` is given in the renaming, the object may or may not exclude null. This is similar to the way that constraints need not match, and **constant** is not specified. The renaming defines a view of the renamed entity, inheriting the original properties.

#### Examples

7 *Example of renaming an object:*

```
8 declare
 L : Person renames Leftmost_Person; -- see 3.10.1
begin
 L.Age := L.Age + 1;
end;
```

#### Wording Changes from Ada 83

- 8.a The phrase “subtype ... as defined in a corresponding object declaration, component declaration, or component subtype indication,” from RM83-8.5(5), is incorrect in Ada 95; therefore we removed it. It is incorrect in the case of an object with an indefinite unconstrained nominal subtype.

#### Incompatibilities With Ada 95

- 8.b/2 {AI95-00363-01} Aliased variables are not necessarily constrained in Ada 2005 (see 3.6). Therefore, a subcomponent of an aliased variable may disappear or change shape, and renaming such a subcomponent thus is illegal, while the same operation would have been legal in Ada 95. Note that most allocated objects are still constrained by their initial value (see 4.8), and thus have no change in the legality of renaming for them. For example, using the type T2 of the previous example:
- 8.c/2
- ```
AT2 : aliased T2;
C1_Ren : Integer renames AT2.C1; -- Illegal in Ada 2005, legal in Ada 95
AT2 := (D1 => True); -- Raised Constraint Error in Ada 95,
-- but does not in Ada 2005, so C1_Ren becomes
-- invalid when this is assigned.
```

Extensions to Ada 95

- 8.d/2 {AI95-00230-01} {AI95-00231-01} {AI95-00254-01} {AI95-00409-01} A renaming can have an anonymous access type. In that case, the accessibility of the renaming is that of the original object (accessibility is not lost as it is for assignment to a component or stand-alone object).
- 8.e/2 {AI95-00231-01} {AI95-00423-01} A renaming can have a `null_exclusion`; if so, the renamed object must also exclude null, so that the `null_exclusion` does not lie. On the other hand, if the renaming does not have a `null_exclusion`, it excludes null if the renamed object does.

Wording Changes from Ada 95

- 8.f/2 {8652/0017} {AI95-00184-01} **Corrigendum:** Fixed to forbid renamings of depends-on-discriminant components if the type *might* be definite.

Incompatibilities With Ada 2005

- 8.g/3 {AI05-0008-1} **Correction:** Simplified the description of when a discriminant-dependent component is allowed to be renamed — it's now simply when the object is known to be constrained. This fixes a confusion as to whether a subcomponent of an object that is not certain to be constrained can be renamed. The fix introduces an incompatibility, as the rule did not apply in Ada 95 if the prefix was a constant; but it now applies no matter what kind of object is involved. The incompatibility is not too bad, since most kinds of constants are known to be constrained.

Extensions to Ada 2005

- 8.h/3 {AI05-0183-1} An optional `aspect_specification` can be used in an `object_renaming_declaration`. This is described in 13.1.1.

8.5.2 Exception Renaming Declarations

[An `exception_renaming_declaration` is used to rename an exception.]

1

Syntax

```
{AI05-0183-1} exception_renaming_declaration ::=
defining_identifier : exception renames exception_name
[aspect_specification];
```

2/3

Legality Rules

The renamed entity shall be an exception.

3

Static Semantics

An `exception_renaming_declaration` declares a new view [of the renamed exception].

4

Examples

Example of renaming an exception:

5

```
EOF : exception renames Ada.IO_Exceptions.End_Error; -- see A.13
```

6

Extensions to Ada 2005

{AI05-0183-1} An optional `aspect_specification` can be used in an `exception_renaming_declaration`. This is described in 13.1.1.

6.a/3

8.5.3 Package Renaming Declarations

[A `package_renaming_declaration` is used to rename a package.]

1

Syntax

```
{AI05-0183-1} package_renaming_declaration ::=
package defining_program_unit_name renames package_name
[aspect_specification];
```

2/3

Legality Rules

The renamed entity shall be a package.

3

{AI95-00217-06} {AI95-00412-01} If the `package_name` of a `package_renaming_declaration` denotes a limited view of a package *P*, then a name that denotes the `package_renaming_declaration` shall occur only within the immediate scope of the renaming or the scope of a `with_clause` that mentions the package *P* or, if *P* is a nested package, the innermost library package enclosing *P*.

3.1/2

Discussion: The use of a renaming that designates a limited view is restricted to locations where we know whether the view is limited or nonlimited (based on a `with_clause`). We don't want to make an implicit limited view, as those are not transitive like a regular view. Implementations should be able to see all limited views needed based on the `context_clause`.

3.a.1/2

Static Semantics

A `package_renaming_declaration` declares a new view [of the renamed package].

4

{AI95-00412-01} [At places where the declaration of the limited view of the renamed package is visible, a name that denotes the `package_renaming_declaration` denotes a limited view of the package (see 10.1.1).]

4.1/2

Proof: This rule is found in 8.3, “Visibility”.

4.a.1/2

Examples

5 *Example of renaming a package:*

6 `package TM renames Table_Manager;`

Wording Changes from Ada 95

6.a/2 {AI95-00217-06} {AI95-00412-01} Uses of renamed limited views of packages can only be used within the scope of a `with_clause` for the renamed package.

Extensions to Ada 2005

6.b/3 {AI05-0183-1} An optional `aspect_specification` can be used in a `package_renaming_declaration`. This is described in 13.1.1.

8.5.4 Subprogram Renaming Declarations

1/3 {AI05-0299-1} A `subprogram_renaming_declaration` can serve as the completion of a `subprogram_declaration`; such a `renaming_declaration` is called a *renaming-as-body*. A `subprogram_renaming_declaration` that is not a completion is called a *renaming-as-declaration*[], and is used to rename a subprogram (possibly an enumeration literal) or an entry].

1.a/3 **Ramification:** {AI05-0299-1} A *renaming-as-body* is a declaration, as defined in Clause 3.

Syntax

2/3 {AI95-00218-03} {AI05-0183-1} `subprogram_renaming_declaration ::=`
`[overriding_indicator]`
`subprogram_specification renames callable_entity_name`
`[aspect_specification];`

Name Resolution Rules

3 The expected profile for the *callable_entity_name* is the profile given in the `subprogram_specification`.

Legality Rules

4/3 {AI05-0239-1} The profile of a *renaming-as-declaration* shall be mode conformant, with that of the renamed callable entity.

4.1/2 {AI95-00423-01} For a parameter or result subtype of the `subprogram_specification` that has an explicit `null_exclusion`:

4.2/2 • if the *callable_entity_name* denotes a generic formal subprogram of a generic unit *G*, and the `subprogram_renaming_declaration` occurs within the body of a generic unit *G* or within the body of a generic unit declared within the declarative region of the generic unit *G*, then the corresponding parameter or result subtype of the formal subprogram of *G* shall have a `null_exclusion`;

4.3/2 • otherwise, the subtype of the corresponding parameter or result type of the renamed callable entity shall exclude null. In addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit.

4.a/2 **Reason:** This rule prevents “lying”. **Null** must never be the value of a parameter or result with an explicit `null_exclusion`. The first bullet is an assume-the-worst rule which prevents trouble in generic bodies (including bodies of child units) when the formal subtype excludes null implicitly.

5/3 {8652/0027} {8652/0028} {AI95-00135-01} {AI95-00145-01} {AI05-0239-1} The profile of a *renaming-as-body* shall conform fully to that of the declaration it completes. If the *renaming-as-body* completes that declaration before the subprogram it declares is frozen, the profile shall be mode conformant with that of the renamed callable entity and the subprogram it declares takes its convention from the renamed subprogram; otherwise, the profile shall be subtype conformant with that of the

renamed callable entity and the convention of the renamed subprogram shall not be Intrinsic. A renaming-as-body is illegal if the declaration occurs before the subprogram whose declaration it completes is frozen, and the renaming renames the subprogram itself, through one or more subprogram renaming declarations, none of whose subprograms has been frozen.

- Reason:** The otherwise part of the second sentence is to allow an implementation of a renaming-as-body as a single jump instruction to the target subprogram. Among other things, this prevents a subprogram from being completed with a renaming of an entry. (In most cases, the target of the jump can be filled in at link time. In some cases, such as a renaming of a name like "A(I).all", an indirect jump is needed. Note that the name is evaluated at renaming time, not at call time.) 5.a/1
- {8652/0028} {AI95-00145-01} The first part of the second sentence is intended to allow renaming-as-body of predefined operators before the `subprogram_declaration` is frozen. For some types (such as integer types), the parameter type for operators is the base type, and it would be very strange for 5.a.1/1
- ```
function Equal (A, B : in T) return Boolean;
function Equal (A, B : in T) return Boolean renames "=";
```
- to be illegal. (Note that predefined operators cannot be renamed this way after the `subprogram_declaration` is frozen, as they have convention Intrinsic.)
- The first sentence is the normal rule for completions of `subprogram_declarations`. 5.b/1
- Ramification:** An `entry_declaration`, unlike a `subprogram_declaration`, cannot be completed with a `renaming_declaration`. Nor can a `generic_subprogram_declaration`. 5.c
- The syntax rules prevent a protected subprogram declaration from being completed by a renaming. This is fortunate, because it allows us to avoid worrying about whether the implicit protected object parameter of a protected operation is involved in the conformance rules. 5.d
- Reason:** {8652/0027} {AI95-00135-01} Circular renames before freezing is illegal, as the compiler would not be able to determine the convention of the subprogram. Other circular renames are handled below; see Bounded (Run-Time) Errors. 5.d.1/1
- {AI95-00228-01} The `callable_entity_name` of a renaming shall not denote a subprogram that requires overriding (see 3.9.3). 5.1/2
- Reason:** {AI95-00228-01} Such a rename cannot be of the inherited subprogram (which requires overriding because it cannot be called), and thus cannot squirrel away a subprogram (see below). That would be confusing, so we make it illegal. The renaming is allowed after the overriding, as then the name will denote the overriding subprogram, not the inherited one. 5.d.2/2
- {AI95-00228-01} The `callable_entity_name` of a renaming-as-body shall not denote an abstract subprogram. 5.2/2
- Reason:** {AI95-00228-01} Such a subprogram has no body, so it hardly can replace one in the program. 5.d.3/2
- A name that denotes a formal parameter of the `subprogram_specification` is not allowed within the `callable_entity_name`. 6
- Reason:** This is to prevent things like this: 6.a
- ```
function F(X : Integer) return Integer renames Table(X).all;
```
- 6.b
- A similar rule in 6.1 forbids things like this: 6.c
- ```
function F(X : Integer; Y : Integer := X) return Integer;
```
- 6.d

#### Static Semantics

A renaming-as-declaration declares a new view of the renamed entity. The profile of this new view takes its subtypes, parameter modes, and calling convention from the original profile of the callable entity, while taking the formal parameter names and `default_expressions` from the profile given in the `subprogram_renaming_declaration`. The new view is a function or procedure, never an entry. 7

**To be honest:** When renaming an entry as a procedure, the compile-time rules apply as if the new view is a procedure, but the run-time semantics of a call are that of an entry call. 7.a

**Ramification:** For example, it is illegal for the `entry_call_statement` of a `timed_entry_call` to call the new view. But what looks like a procedure call will do things like barrier waiting. 7.b

- 7.b.1/3 {8652/0105} {AI95-00211-01} {AI95-00228-01} {AI05-0095-1} All properties of the renamed entity are inherited by the new view unless otherwise stated by this International Standard. In particular, if the renamed entity is abstract, the new view also is abstract. Similarly, if the renamed entity is not a program unit, then neither is the renaming. (Implicitly declared subprograms are not program units, see 10.1).

*Dynamic Semantics*

- 7.1/1 {8652/0014} {AI95-00064-01} For a call to a subprogram whose body is given as a renaming-as-body, the execution of the renaming-as-body is equivalent to the execution of a `subprogram_body` that simply calls the renamed subprogram with its formal parameters as the actual parameters and, if it is a function, returns the value of the call.
- 7.b.2/1 **Ramification:** This implies that the subprogram completed by the renaming-as-body has its own elaboration check.
- 8/3 {AI05-0123-1} For a call on a renaming of a dispatching subprogram that is overridden, if the overriding occurred before the renaming, then the body executed is that of the overriding declaration, even if the overriding declaration is not visible at the place of the renaming; otherwise, the inherited or predefined subprogram is called. A corresponding rule applies to a call on a renaming of a predefined equality operator for an untagged record type.
- 8.a **Discussion:** Note that whether or not the renaming is itself primitive has nothing to do with the renamed subprogram.
- 8.b/3 {AI05-0123-1} Note that the above rule is only for tagged types and equality of untagged record types.
- 8.c Consider the following example:
- 8.d
- ```

package P is
  type T is tagged null record;
  function Predefined_Equal(X, Y : T) return Boolean renames "=";
private
  function "="(X, Y : T) return Boolean; -- Override predefined "="
end P;

```
- 8.e
- ```

with P; use P;
package Q is
 function User_Defined_Equal(X, Y : T) return Boolean renames P."=";
end Q;

```
- 8.f A call on `Predefined_Equal` will execute the predefined equality operator of T, whereas a call on `User_Defined_Equal` will execute the body of the overriding declaration in the private part of P.
- 8.g Thus a renaming allows one to squirrel away a copy of an inherited or predefined subprogram before later overriding it.

*Bounded (Run-Time) Errors*

- 8.1/1 {8652/0027} {AI95-00135-01} If a subprogram directly or indirectly renames itself, then it is a bounded error to call that subprogram. Possible consequences are that `Program_Error` or `Storage_Error` is raised, or that the call results in infinite recursion.
- 8.g.1/1 **Reason:** {8652/0027} {AI95-00135-01} This has to be a bounded error, as it is possible for a renaming-as-body appearing in a package body to cause this problem. Thus it is not possible in general to detect this problem at compile time.

NOTES

- 9 12 A procedure can only be renamed as a procedure. A function whose `defining_designator` is either an `identifier` or an `operator_symbol` can be renamed with either an `identifier` or an `operator_symbol`; for renaming as an operator, the subprogram specification given in the `renaming_declaration` is subject to the rules given in 6.6 for operator declarations. Enumeration literals can be renamed as functions; similarly, `attribute_references` that denote functions (such as references to `Succ` and `Pred`) can be renamed as functions. An entry can only be renamed as a procedure; the new `name` is only allowed to appear in contexts that allow a procedure `name`. An entry of a family can be renamed, but an entry family cannot be renamed as a whole.
- 10 13 The operators of the root numeric types cannot be renamed because the types in the profile are anonymous, so the corresponding specifications cannot be written; the same holds for certain attributes, such as `Pos`.
- 11 14 Calls with the new `name` of a renamed entry are `procedure_call_statements` and are not allowed at places where the syntax requires an `entry_call_statement` in `conditional_` and `timed_entry_calls`, nor in an `asynchronous_select`; similarly, the `Count` attribute is not available for the new `name`.

15 The primitiveness of a renaming-as-declaration is determined by its profile, and by where it occurs, as for any declaration of (a view of) a subprogram; primitiveness is not determined by the renamed view. In order to perform a dispatching call, the subprogram name has to denote a primitive subprogram, not a nonprimitive renaming of a primitive subprogram. 12

**Reason:** A `subprogram_renaming_declaration` could more properly be called `renaming_as_subprogram_declaration`, since you're renaming something as a subprogram, but you're not necessarily renaming a subprogram. But that's too much of a mouthful. Or, alternatively, we could call it a `callable_entity_renaming_declaration`, but that's even worse. Not only is it a mouthful, it emphasizes the entity being renamed, rather than the new view, which we think is a bad idea. We'll live with the oddity. 12.a

#### Examples

*Examples of subprogram renaming declarations:* 13

```

procedure My_Write(C : in Character) renames Pool(K).Write; -- see 4.1.3 14
function Real_Plus(Left, Right : Real) return Real renames "+"; 15
function Int_Plus (Left, Right : Integer) return Integer renames "+";
function Rouge return Color renames Red; -- see 3.5.1 16
function Rot return Color renames Red;
function Rosso return Color renames Rouge;
function Next(X : Color) return Color renames Color'Succ; -- see 3.5.1 17

```

*Example of a subprogram renaming declaration with new parameter names:* 18

```

function "*" (X,Y : Vector) return Real renames Dot_Product; -- see 6.1 19

```

*Example of a subprogram renaming declaration with a new default expression:* 20

```

function Minimum(L : Link := Head) return Cell renames Min_Cell; -- see 6.1 21

```

#### Extensions to Ada 95

{8652/0028} {AI95-00145-01} **Corrigendum:** Allowed a renaming-as-body to be just mode conformant with the specification if the subprogram is not yet frozen. 21.a/2

{AI95-00218-03} **Overriding\_indicator** (see 8.3.1) is optionally added to subprogram renamings. 21.b/2

#### Wording Changes from Ada 95

{8652/0014} {AI95-00064-01} **Corrigendum:** Described the semantics of renaming-as-body, so that the location of elaboration checks is clear. 21.c/2

{8652/0027} {AI95-00135-01} **Corrigendum:** Clarified that circular renaming-as-body is illegal (if it can be detected in time) or a bounded error. 21.d/2

{AI95-00228-01} **Amendment Correction:** Clarified that renaming a shall-be-overridden subprogram is illegal, as well as renaming-as-body an abstract subprogram. 21.e/2

{AI95-00423-01} Added matching rules for `null_exclusions`. 21.f/2

#### Inconsistencies With Ada 2005

{AI05-0123-1} Renaming of user-defined untagged record equality is now defined to call the overridden body so long as the overriding occurred before the renames. This could change the body called in unusual cases; the change is necessary to preserve the principle that the body called for an explicit call to "=" (via a renames in this case) is the same as the one inherited for a derived type and used in generics. Note that any renamings before the overriding will be unchanged. Any differences caused by the change will be rare and most likely will fix a bug. 21.f.1/3

#### Extensions to Ada 2005

{AI05-0183-1} An optional `aspect_specification` can be used in a `subprogram_renaming_declaration`. This is described in 13.1.1. 21.g/3

## 8.5.5 Generic Renaming Declarations

[A `generic_renaming_declaration` is used to rename a generic unit.] 1

*Syntax*

2/3 `{AI05-0183-1} generic_renaming_declaration ::=`  
`generic package      defining_program_unit_name renames generic_package_name`  
`[aspect_specification];`  
`| generic procedure  defining_program_unit_name renames generic_procedure_name`  
`[aspect_specification];`  
`| generic function   defining_program_unit_name renames generic_function_name`  
`[aspect_specification];`

*Legality Rules*

3 The renamed entity shall be a generic unit of the corresponding kind.

*Static Semantics*

4 A `generic_renaming_declaration` declares a new view [of the renamed generic unit].

## NOTES

5 16 Although the properties of the new view are the same as those of the renamed view, the place where the `generic_renaming_declaration` occurs may affect the legality of subsequent renamings and instantiations that denote the `generic_renaming_declaration`, in particular if the renamed generic unit is a library unit (see 10.1.1).

*Examples*

6 *Example of renaming a generic unit:*

7 `generic package Enum_IO renames Ada.Text_IO.Enumeration_IO;  -- see A.10.10`

*Extensions to Ada 83*

7.a Renaming of generic units is new to Ada 95. It is particularly important for renaming child library units that are generic units. For example, it might be used to rename `Numerics.Generic_Elementary_Functions` as simply `Generic_Elementary_Functions`, to match the name for the corresponding Ada-83-based package.

*Wording Changes from Ada 83*

7.b The information in RM83-8.6, “The Package Standard,” has been updated for the child unit feature, and moved to Annex A, except for the definition of “predefined type,” which has been moved to 3.2.1.

*Extensions to Ada 2005*

7.c/3 `{AI05-0183-1}` An optional `aspect_specification` can be used in a `generic_renaming_declaration`. This is described in 13.1.1.

## 8.6 The Context of Overload Resolution

1/3 `{AI05-0299-1}` [ Because declarations can be overloaded, it is possible for an occurrence of a usage name to have more than one possible interpretation; in most cases, ambiguity is disallowed. This subclause describes how the possible interpretations resolve to the actual interpretation.

2 Certain rules of the language (the Name Resolution Rules) are considered “overloading rules”. If a possible interpretation violates an overloading rule, it is assumed not to be the intended interpretation; some other possible interpretation is assumed to be the actual interpretation. On the other hand, violations of nonoverloading rules do not affect which interpretation is chosen; instead, they cause the construct to be illegal. To be legal, there usually has to be exactly one acceptable interpretation of a construct that is a “complete context”, not counting any nested complete contexts.

3 The syntax rules of the language and the visibility rules given in 8.3 determine the possible interpretations. Most type checking rules (rules that require a particular type, or a particular class of types, for example) are overloading rules. Various rules for the matching of formal and actual parameters are overloading rules.]

## Language Design Principles

The type resolution rules are intended to minimize the need for implicit declarations and preference rules associated with implicit conversion and dispatching operations. 3.a

## Name Resolution Rules

[Overload resolution is applied separately to each *complete context*, not counting inner complete contexts.] Each of the following constructs is a *complete context*: 4

- A `context_item`. 5
- A `declarative_item` or declaration. 6
  - Ramification:** A `loop_parameter_specification` is a declaration, and hence a complete context. 6.a
- A `statement`. 7
- A `pragma_argument_association`. 8
  - Reason:** We would make it the whole `pragma`, except that certain `pragma` arguments are allowed to be ambiguous, and ambiguity applies to a complete context. 8.a
- The expression of a `case_statement`. 9
  - Ramification:** This means that the expression is resolved without looking at the choices. 9.a

An (overall) *interpretation* of a complete context embodies its meaning, and includes the following information about the constituents of the complete context, not including constituents of inner complete contexts: 10

- for each constituent of the complete context, to which syntactic categories it belongs, and by which syntax rules; and 11
  - Ramification:** Syntactic categories is plural here, because there are lots of trivial productions — an expression might also be all of the following, in this order: identifier, name, primary, factor, term, simple\_expression, and relation. Basically, we're trying to capture all the information in the parse tree here, without using compiler-writer's jargon like “parse tree”. 11.a
- for each usage name, which declaration it denotes (and, therefore, which view and which entity it denotes); and 12
  - Ramification:** {A195-00382-01} In most cases, a usage name denotes the view declared by the denoted declaration. However, in certain cases, a usage name that denotes a declaration and appears inside the declarative region of that same declaration, denotes the current instance of the declaration. For example, within a `task_body` other than in an `access_definition`, a usage name that denotes the `task_type_declaration` denotes the object containing the currently executing task, and not the task type declared by the declaration. 12.a/2
- for a complete context that is a `declarative_item`, whether or not it is a completion of a declaration, and (if so) which declaration it completes. 13
  - Ramification:** Unfortunately, we are not confident that the above list is complete. We'll have to live with that. 13.a
  - To be honest:** For “possible” interpretations, the above information is tentative. 13.b
  - Discussion:** A possible interpretation (an *input* to overload resolution) contains information about what a usage name *might* denote, but what it actually *does* denote requires overload resolution to determine. Hence the term “tentative” is needed for possible interpretations; otherwise, the definition would be circular. 13.c

A *possible interpretation* is one that obeys the syntax rules and the visibility rules. An *acceptable interpretation* is a possible interpretation that obeys the *overloading rules*[, that is, those rules that specify an expected type or expected profile, or specify how a construct shall *resolve* or be *interpreted*.] 14

- To be honest:** One rule that falls into this category, but does not use the above-mentioned magic words, is the rule about numbers of parameter associations in a call (see 6.4). 14.a
- Ramification:** The Name Resolution Rules are the ones that appear under the Name Resolution Rules heading. Some Syntax Rules are written in English, instead of BNF. No rule is a Syntax Rule or Name Resolution Rule unless it appears under the appropriate heading. 14.b

15 The *interpretation* of a constituent of a complete context is determined from the overall interpretation of the complete context as a whole. [Thus, for example, “interpreted as a `function_call`,” means that the construct’s interpretation says that it belongs to the syntactic category `function_call`.]

16 [Each occurrence of] a usage name *denotes* the declaration determined by its interpretation. It also denotes the view declared by its denoted declaration, except in the following cases:

16.a **Ramification:** As explained below, a pragma argument is allowed to be ambiguous, so it can denote several declarations, and all of the views declared by those declarations.

- 17/3 • *{AI95-00382-01} {AI05-0287-1}* If a usage name appears within the declarative region of a `type_declaration` and denotes that same `type_declaration`, then it denotes the *current instance* of the type (rather than the type itself); the current instance of a type is the object or value of the type that is associated with the execution that evaluates the usage name. Similarly, if a usage name appears within the declarative region of a `subtype_declaration` and denotes that same `subtype_declaration`, then it denotes the current instance of the subtype. These rules do not apply if the usage name appears within the `subtype_mark` of an `access_definition` for an access-to-object type, or within the subtype of a parameter or result of an access-to-subprogram type.

17.a/2 **Reason:** *{AI95-00382-01}* This is needed, for example, for references to the `Access` attribute from within the `type_declaration`. Also, within a `task_body` or `protected_body`, we need to be able to denote the current task or protected object. (For a `single_task_declaration` or `single_protected_declaration`, the rule about current instances is not needed.) We exclude anonymous access types so that they can be used to create self-referencing types in the natural manner (otherwise such types would be illegal).

17.b/2 **Discussion:** *{AI95-00382-01}* The phrase “within the `subtype_mark`” in the “this rule does not apply” part is intended to cover a case like `access T'Class` appearing within the declarative region of `T`: here `T` denotes the type, not the current instance.

- 18 • If a usage name appears within the declarative region of a `generic_declaration` (but not within its `generic_formal_part`) and it denotes that same `generic_declaration`, then it denotes the *current instance* of the generic unit (rather than the generic unit itself). See also 12.3.

18.a **To be honest:** The current instance of a generic unit is the instance created by whichever `generic_instantiation` is of interest at any given time.

18.b **Ramification:** Within a `generic_formal_part`, a name that denotes the `generic_declaration` denotes the generic unit, which implies that it is not overloadable.

19 A usage name that denotes a view also denotes the entity of that view.

19.a **Ramification:** Usually, a usage name denotes only one declaration, and therefore one view and one entity.

20/2 *{AI95-00231-01}* The *expected type* for a given `expression`, `name`, or other construct determines, according to the *type resolution rules* given below, the types considered for the construct during overload resolution. [The type resolution rules provide support for class-wide programming, universal literals, dispatching operations, and anonymous access types:]

20.a **Ramification:** Expected types are defined throughout the RM95. The most important definition is that, for a subprogram, the expected type for the actual parameter is the type of the formal parameter.

20.b The type resolution rules are trivial unless either the actual or expected type is universal, class-wide, or of an anonymous access type.

- 21 • If a construct is expected to be of any type in a class of types, or of the universal or class-wide type for a class, then the type of the construct shall resolve to a type in that class or to a universal type that covers the class.

21.a **Ramification:** This matching rule handles (among other things) cases like the `Val` attribute, which denotes a function that takes a parameter of type *universal\_integer*.

21.b/1 The last part of the rule, “or to a universal type that covers the class” implies that if the expected type for an expression is *universal\_fixed*, then an expression whose type is *universal\_real* (such as a real literal) is OK.

- 22 • If the expected type for a construct is a specific type *T*, then the type of the construct shall resolve either to *T*, or:

- Ramification:** This rule is *not* intended to create a preference for the specific type — such a preference would cause Beaujolais effects. 22.a
- to *T*Class; or 23
- Ramification:** This will only be legal as part of a call on a dispatching operation; see 3.9.2, “Dispatching Operations of Tagged Types”. Note that that rule is not a Name Resolution Rule. 23.a
- to a universal type that covers *T*; or 24
  - *{AI95-00230-01}* *{AI95-00231-01}* *{AI95-00254-01}* *{AI95-00409-01}* when *T* is a specific anonymous access-to-object type (see 3.10) with designated type *D*, to an access-to-object type whose designated type is *D*'Class or is covered by *D*; or 25/2
- This paragraph was deleted. {AI95-00409-01}* 25.a/2
- Ramification:** The case where the actual is access-to-*D*'Class will only be legal as part of a call on a dispatching operation; see 3.9.2, “Dispatching Operations of Tagged Types”. Note that that rule is not a Name Resolution Rule. 25.b
- *{AI05-0149-1}* when *T* is a named general access-to-object type (see 3.10) with designated type *D*, to an anonymous access-to-object type whose designated type covers or is covered by *D*; or 25.1/3
  - *{AI95-00254-01}* *{AI95-00409-01}* *{AI05-0239-1}* when *T* is an anonymous access-to-subprogram type (see 3.10), to an access-to-subprogram type whose designated profile is type conformant with that of *T*. 25.2/3
- In certain contexts, [such as in a `subprogram_renaming_declaration`,] the Name Resolution Rules define an *expected profile* for a given `name`; in such cases, the `name` shall resolve to the name of a callable entity whose profile is type conformant with the expected profile. 26
- Ramification:** *{AI05-0239-1}* The parameter and result *subtypes* are not used in overload resolution. Only type conformance of profiles is considered during overload resolution. Legality rules generally require at least mode conformance in addition, but those rules are not used in overload resolution. 26.a/3
- Legality Rules*
- {AI95-00332-01}* When a construct is one that requires that its expected type be a *single* type in a given class, the type of the construct shall be determinable solely from the context in which the construct appears, excluding the construct itself, but using the requirement that it be in the given class. Furthermore, the context shall not be one that expects any type in some class that contains types of the given class; in particular, the construct shall not be the operand of a `type_conversion`. 27/2
- Ramification:** *{AI95-00230-01}* For example, the expected type for a string literal is required to be a single string type. But the expected type for the operand of a `type_conversion` is any type. Therefore, a string literal is not allowed as the operand of a `type_conversion`. This is true even if there is only one string type in scope (which is never the case). The reason for these rules is so that the compiler will not have to search “everywhere” to see if there is exactly one type in a class in scope. 27.a/2
- Discussion:** *{AI95-00332-01}* The first sentence is carefully worded so that it only mentions “expected type” as part of identifying the interesting case, but doesn't require that the context actually provide such an expected type. This allows such constructs to be used inside of constructs that don't provide an expected type (like qualified expressions and renames). Otherwise, such constructs wouldn't allow `aggregates`, `'Access`, and so on. 27.b/2
- {AI05-0102-1}* *{AI05-0149-1}* *{AI05-0299-1}* Other than for the `simple_expression` of a membership test, if the expected type for a `name` or `expression` is not the same as the actual type of the `name` or `expression`, the actual type shall be convertible to the expected type (see 4.6); further, if the expected type is a named access-to-object type with designated type *D1* and the actual type is an anonymous access-to-object type with designated type *D2*, then *D1* shall cover *D2*, and the `name` or `expression` shall denote a view with an accessibility level for which the statically deeper relationship applies[; in particular it shall not denote an access parameter nor a stand-alone access object]. 27.1/3
- Reason:** This rule prevents an implicit conversion that would be illegal if it was an explicit conversion. For instance, this prevents assigning an access-to-constant value into a stand-alone anonymous access-to-variable object. It also covers convertibility of the designated type and accessibility checks. 27.c/3

- 27.d/3 The rule also minimizes cases of implicit conversions when the tag check or the accessibility check might fail. We word it this way because access discriminants should also be disallowed if their enclosing object is designated by an access parameter.
- 27.e/3 **Ramification:** This rule does not apply to expressions that don't have expected types (such as the operand of a qualified expression or the expression of a renames). We don't need a rule like this in those cases, as the type needs to be the same; there is no implicit conversion.
- 28 A complete context shall have at least one acceptable interpretation; if there is exactly one, then that one is chosen.
- 28.a **Ramification:** This, and the rule below about ambiguity, are the ones that suck in all the Syntax Rules and Name Resolution Rules as compile-time rules. Note that this and the ambiguity rule have to be Legality Rules.
- 29 There is a *preference* for the primitive operators (and ranges) of the root numeric types *root\_integer* and *root\_real*. In particular, if two acceptable interpretations of a constituent of a complete context differ only in that one is for a primitive operator (or range) of the type *root\_integer* or *root\_real*, and the other is not, the interpretation using the primitive operator (or range) of the root numeric type is *preferred*.
- 29.a **Reason:** The reason for this preference is so that expressions involving literals and named numbers can be unambiguous. For example, without the preference rule, the following would be ambiguous:
- 29.b/1 

```
N : constant := 123;
if N > 100 then -- Preference for root_integer ">" operator.
 ...
end if;
```
- 29.1/3 {AI05-0149-1} Similarly, there is a preference for the equality operators of the *universal\_access* type (see 4.5.2). If two acceptable interpretations of a constituent of a complete context differ only in that one is for an equality operator of the *universal\_access* type, and the other is not, the interpretation using the equality operator of the *universal\_access* type is preferred.
- 29.c/3 **Reason:** This preference is necessary because of implicit conversion from an anonymous access type to a named access type, which would allow the equality operator of any named access type to be used to compare anonymous access values (and that way lies madness).
- 30 For a complete context, if there is exactly one overall acceptable interpretation where each constituent's interpretation is the same as or preferred (in the above sense) over those in all other overall acceptable interpretations, then that one overall acceptable interpretation is chosen. Otherwise, the complete context is *ambiguous*.
- 31 A complete context other than a *pragma\_argument\_association* shall not be ambiguous.
- 32 A complete context that is a *pragma\_argument\_association* is allowed to be ambiguous (unless otherwise specified for the particular pragma), but only if every acceptable interpretation of the pragma argument is as a *name* that statically denotes a callable entity. Such a *name* denotes all of the declarations determined by its interpretations, and all of the views declared by these declarations.
- 32.a/3 **Ramification:** {AI95-00224-01} {AI05-0229-1} This applies to Inline, Suppress, Import, Export, and Convention pragmas. For example, it is OK to say “**pragma** Export(C, Entity\_Name => P.Q);”, even if there are two directly visible P's, and there are two Q's declared in the visible part of each P. In this case, P.Q denotes four different declarations. This rule also applies to certain pragmas defined in the Specialized Needs Annexes. It almost applies to Pure, Elaborate\_Body, and Elaborate\_All pragmas, but those can't have overloading for other reasons. Note that almost all of these pragmas are obsolescent (see J.10 and J.15), and a major reason is that this rule has proven to be too broad in practice (it is common to want to specify something on a single subprogram of an overloaded set, that can't be done easily with this rule). Aspect\_specifications, which are given on individual declarations, are preferred in Ada 2012.
- 32.b Note that if a pragma argument denotes a *call* to a callable entity, rather than the entity itself, this exception does not apply, and ambiguity is disallowed.
- 32.c Note that we need to carefully define which pragma-related rules are Name Resolution Rules, so that, for example, a **pragma** Inline does not pick up subprograms declared in enclosing declarative regions, and therefore make itself illegal.
- 32.d We say “statically denotes” in the above rule in order to avoid having to worry about how many times the name is evaluated, in case it denotes more than one callable entity.

## NOTES

17 If a usage name has only one acceptable interpretation, then it denotes the corresponding entity. However, this does not mean that the usage name is necessarily legal since other requirements exist which are not considered for overload resolution; for example, the fact that an expression is static, whether an object is constant, mode and subtype conformance rules, freezing rules, order of elaboration, and so on. 33

Similarly, subtypes are not considered for overload resolution (the violation of a constraint does not make a program illegal but raises an exception during program execution). 34

*Incompatibilities With Ada 83*

The new preference rule for operators of root numeric types is upward incompatible, but only in cases that involved *Beaujolais* effects in Ada 83. Such cases are ambiguous in Ada 95. 34.a

*Extensions to Ada 83*

The rule that allows an expected type to match an actual expression of a universal type, in combination with the new preference rule for operators of root numeric types, subsumes the Ada 83 "implicit conversion" rules for universal types. 34.b

*Wording Changes from Ada 83*

In Ada 83, it is not clear what the "syntax rules" are. AI83-00157 states that a certain textual rule is a syntax rule, but it's still not clear how one tells in general which textual rules are syntax rules. We have solved the problem by stating exactly which rules are syntax rules — the ones that appear under the "Syntax" heading. 34.c

RM83 has a long list of the "forms" of rules that are to be used in overload resolution (in addition to the syntax rules). It is not clear exactly which rules fall under each form. We have solved the problem by explicitly marking all rules that are used in overload resolution. Thus, the list of kinds of rules is unnecessary. It is replaced with some introductory (intentionally vague) text explaining the basic idea of what sorts of rules are overloading rules. 34.d

{AI05-0299-1} It is not clear from RM83 what information is embodied in a "meaning" or an "interpretation." "Meaning" and "interpretation" were intended to be synonymous; we now use the latter only in defining the rules about overload resolution. "Meaning" is used only informally. This subclause attempts to clarify what is meant by "interpretation." 34.e/3

For example, RM83 does not make it clear that overload resolution is required in order to match `subprogram_bodies` with their corresponding declarations (and even to tell whether a given `subprogram_body` is the completion of a previous declaration). Clearly, the information needed to do this is part of the "interpretation" of a `subprogram_body`. The resolution of such things is defined in terms of the "expected profile" concept. Ada 95 has some new cases where expected profiles are needed — the resolution of P'Access, where P might denote a subprogram, is an example. 34.f

RM83-8.7(2) might seem to imply that an interpretation embodies information about what is denoted by each usage name, but not information about which syntactic category each construct belongs to. However, it seems necessary to include such information, since the Ada grammar is highly ambiguous. For example, X(Y) might be a `function_call` or an `indexed_component`, and no context-free/syntactic information can tell the difference. It seems like we should view X(Y) as being, for example, "interpreted as a `function_call`" (if that's what overload resolution decides it is). Note that there are examples where the denotation of each usage name does not imply the syntactic category. However, even if that were not true, it seems that intuitively, the interpretation includes that information. Here's an example: 34.g

```

type T;
type A is access T;
type T is array(Integer range 1..10) of A;
I : Integer := 3;
function F(X : Integer := 7) return A;
Y : A := F(I); -- Ambiguous? (We hope so.)

```

Consider the declaration of Y (a complete context). In the above example, overload resolution can easily determine the declaration, and therefore the entity, denoted by Y, A, F, and I. However, given all of that information, we still don't know whether F(I) is a `function_call` or an `indexed_component` whose prefix is a `function_call`. (In the latter case, it is equivalent to F(7).`all`(I).) 34.i/1

It seems clear that the declaration of Y ought to be considered ambiguous. We describe that by saying that there are two interpretations, one as a `function_call`, and one as an `indexed_component`. These interpretations are both acceptable to the overloading rules. Therefore, the complete context is ambiguous, and therefore illegal. 34.j

It is the intent that the Ada 95 preference rule for root numeric operators is more locally enforceable than that of RM83-4.6(15). It should also eliminate interpretation shifts due to the addition or removal of a `use_clause` (the so called *Beaujolais* effect). 34.k

{AI95-00114-01} RM83-8.7 seems to be missing some complete contexts, such as `pragma_argument_associations`, `declarative_items` that are not declarations or `aspect_clauses`, and `context_items`. We have added these, and also 34.l/2

replaced the “must be determinable” wording of RM83-5.4(3) with the notion that the expression of a `case_statement` is a complete context.

- 34.m Cases like the `Val` attribute are now handled using the normal type resolution rules, instead of having special cases that explicitly allow things like “any integer type.”

*Incompatibilities With Ada 95*

- 34.n/2 *{AI95-00409-01}* Ada 95 allowed name resolution to distinguish between anonymous access-to-variable and access-to-constant types. This is similar to distinguishing between subprograms with `in` and `in out` parameters, which is known to be bad. Thus, that part of the rule was dropped as we now have anonymous access-to-constant types, making this much more likely.

- 34.o/2 

```
type Cacc is access constant Integer;
procedure Proc (Acc : access Integer) ...
procedure Proc (Acc : Cacc) ...
List : Cacc := ...;
Proc (List); -- OK in Ada 95, ambiguous in Ada 2005.
```

- 34.p/2 If there is any code like this (such code should be rare), it will be ambiguous in Ada 2005.

*Extensions to Ada 95*

- 34.q/2 *{AI95-00230-01}* *{AI95-00231-01}* *{AI95-00254-01}* Generalized the anonymous access resolution rules to support the new capabilities of anonymous access types (that is, access-to-subprogram and access-to-constant).

- 34.r/2 *{AI95-00382-01}* We now allow the creation of self-referencing types via anonymous access types. This is an extension in unusual cases involving task and protected types. For example:

- 34.s/2 

```
task type T;
```
- 34.t/2 

```
task body T is
 procedure P (X : access T) is -- Illegal in Ada 95, legal in Ada 2005
 ...
 end P;
begin
 ...
end T;
```

*Wording Changes from Ada 95*

- 34.u/2 *{AI95-00332-01}* Corrected the “single expected type” so that it works in contexts that don't have expected types (like object renames and qualified expressions). This fixes a hole in Ada 95 that appears to prohibit using `aggregates`, `'Access`, character literals, string literals, and `allocators` in qualified expressions.

*Incompatibilities With Ada 2005*

- 34.v/3 *{AI05-0149-1}* Implicit conversion is now allowed from anonymous access-to-object types to general access-to-object types. Such conversions can make calls ambiguous. That can only happen when there are two visible subprograms with the same name and have profiles that differ only by a parameter that is of a named or anonymous access type, and the actual argument is of an anonymous access type. This should be rare, as many possible calls would be ambiguous even in Ada 2005 (including `allocators` and any actual of a named access type if the designated types are the same).

*Extensions to Ada 2005*

- 34.w/3 *{AI05-0149-1}* Implicit conversion is allowed from anonymous access-to-object types to general access-to-object types if the designated type is convertible and runtime checks are minimized. See also the incompatibilities section.

*Wording Changes from Ada 2005*

- 34.x/3 *{AI05-0102-1}* Added a requirement here that implicit conversions are convertible to the appropriate type. This rule was scattered about the Standard, we moved a single generalized version here.

## 9 Tasks and Synchronization

{AI05-0299-1} The execution of an Ada program consists of the execution of one or more *tasks*. Each task represents a separate thread of control that proceeds independently and concurrently between the points where it *interacts* with other tasks. The various forms of task interaction are described in this clause, and include: 1/3

**To be honest:** The execution of an Ada program consists of the execution of one or more partitions (see 10.2), each of which in turn consists of the execution of an environment task and zero or more subtasks. 1.a

- the activation and termination of a task; 2
- a call on a protected subprogram of a *protected object*, providing exclusive read-write access, or concurrent read-only access to shared data; 3
- a call on an entry, either of another task, allowing for synchronous communication with that task, or of a protected object, allowing for asynchronous communication with one or more other tasks using that same protected object; 4
- a timed operation, including a simple delay statement, a timed entry call or accept, or a timed asynchronous select statement (see next item); 5
- an asynchronous transfer of control as part of an asynchronous select statement, where a task stops what it is doing and begins execution at a different point in response to the completion of an entry call or the expiration of a delay; 6
- an abort statement, allowing one task to cause the termination of another task. 7

In addition, tasks can communicate indirectly by reading and updating (unprotected) shared variables, presuming the access is properly synchronized through some other kind of task interaction. 8

### *Static Semantics*

The properties of a task are defined by a corresponding task declaration and `task_body`, which together define a program unit called a *task unit*. 9

### *Dynamic Semantics*

Over time, tasks proceed through various *states*. A task is initially *inactive*; upon activation, and prior to its *termination* it is either *blocked* (as part of some task interaction) or *ready* to run. While ready, a task competes for the available *execution resources* that it requires to run. 10

**Discussion:** {AI05-0229-1} The means for selecting which of the ready tasks to run, given the currently available execution resources, is determined by the *task dispatching policy* in effect, which is generally implementation defined, but may be controlled by aspects, pragmas, and operations defined in the Real-Time Annex (see D.2 and D.5). 10.a/3

### NOTES

1 Concurrent task execution may be implemented on multicomputers, multiprocessors, or with interleaved execution on a single physical processor. On the other hand, whenever an implementation can determine that the required semantic effects can be achieved when parts of the execution of a given task are performed by different physical processors acting in parallel, it may choose to perform them in this way. 11

### *Wording Changes from Ada 83*

The introduction has been rewritten. 11.a

We use the term "concurrent" rather than "parallel" when talking about logically independent execution of threads of control. The term "parallel" is reserved for referring to the situation where multiple physical processors run simultaneously. 11.b

## 9.1 Task Units and Task Objects

- 1 A task unit is declared by a *task declaration*, which has a corresponding *task\_body*. A task declaration may be a *task\_type\_declaration*, in which case it declares a named task type; alternatively, it may be a *single\_task\_declaration*, in which case it defines an anonymous task type, as well as declaring a named task object of that type.

### Syntax

- 2/3  $\{AI95-00345-01\}$   $\{AI05-0183-1\}$  *task\_type\_declaration* ::=  
**task type** *defining\_identifier* [*known\_discriminant\_part*]  
 [*aspect\_specification*] [*is*  
 [**new interface\_list with**  
*task\_definition*];
- 3/3  $\{AI95-00399-01\}$   $\{AI05-0183-1\}$  *single\_task\_declaration* ::=  
**task** *defining\_identifier*  
 [*aspect\_specification*][*is*  
 [**new interface\_list with**  
*task\_definition*];
- 4 *task\_definition* ::=  
 {*task\_item*}  
 [**private**  
 {*task\_item*}]  
**end** [*task\_identifier*]
- 5/1  $\{8652/0009\}$   $\{AI95-00137-01\}$  *task\_item* ::= *entry\_declaration* | *aspect\_clause*
- 6/3  $\{AI05-0267-1\}$  *task\_body* ::=  
**task body** *defining\_identifier*  
 [*aspect\_specification*] **is**  
*declarative\_part*  
**begin**  
*handled\_sequence\_of\_statements*  
**end** [*task\_identifier*];

- 7 If a *task\_identifier* appears at the end of a *task\_definition* or *task\_body*, it shall repeat the *defining\_identifier*.

8.a/2 *This paragraph was deleted.*

*Paragraph 8 was deleted.*

### Static Semantics

- 9 A *task\_definition* defines a task type and its first subtype. The first list of *task\_items* of a *task\_definition*, together with the *known\_discriminant\_part*, if any, is called the visible part of the task unit. [ The optional list of *task\_items* after the reserved word **private** is called the private part of the task unit.]
- 9.a/3 **Proof:**  $\{AI05-0299-1\}$  Private part is defined in Clause 8.
- 9.1/1  $\{8652/0029\}$   $\{AI95-00116-01\}$  For a task declaration without a *task\_definition*, a *task\_definition* without *task\_items* is assumed.
- 9.2/3  $\{AI95-00345-01\}$   $\{AI95-00397-01\}$   $\{AI95-00399-01\}$   $\{AI95-00419-01\}$   $\{AI05-0042-1\}$  For a task declaration with an *interface\_list*, the task type inherits user-defined primitive subprograms from each progenitor type (see 3.9.4), in the same way that a derived type inherits user-defined primitive subprograms from its progenitor types (see 3.4). If the first parameter of a primitive inherited subprogram

is of the task type or an access parameter designating the task type, and there is an `entry_declaration` for a single entry with the same identifier within the task declaration, whose profile is type conformant with the prefixed view profile of the inherited subprogram, the inherited subprogram is said to be *implemented* by the conforming task entry using an implicitly declared nonabstract subprogram which has the same profile as the inherited subprogram and which overrides it.

**Ramification:** The inherited subprograms can only come from an interface given as part of the task declaration. 9.b/2

**Reason:** {AI05-0042-1} The part about the implicitly declared subprogram is needed so that a subprogram implemented by an entry is considered to be overridden for the purpose of the other rules of the language. Without it, it would for instance be illegal for an abstract subprogram to be implemented by an entry, because the abstract subprogram would not be overridden. The Legality Rules below ensure that there is no conflict between the implicit overriding subprogram and a user-defined overriding subprogram. 9.b.1/3

#### Legality Rules

{AI95-00345-01} A task declaration requires a completion[, which shall be a `task_body`,] and every `task_body` shall be the completion of some task declaration. 9.3/2

**To be honest:** {AI05-0229-1} If the implementation supports it, the task body can be imported (using aspect `Import`, see B.1), in which case no explicit `task_body` is allowed. 9.c/3

{AI95-00345-01} {AI95-00399-01} [Each `interface_subtype_mark` of an `interface_list` appearing within a task declaration shall denote a limited interface type that is not a protected interface.] 9.4/2

**Proof:** 3.9.4 requires that an `interface_list` only name interface types, and limits the descendants of the various kinds of interface types. Only a limited, task, or synchronized interface can have a task type descendant. Nonlimited or protected interfaces are not allowed, as they offer operations that a task does not have. 9.d/2

{AI95-00397-01} {AI05-0090-1} The prefixed view profile of an explicitly declared primitive subprogram of a tagged task type shall not be type conformant with any entry of the task type, if the subprogram has the same defining name as the entry and the first parameter of the subprogram is of the task type or is an access parameter designating the task type. 9.5/3

**Reason:** This prevents the existence of two operations with the same name and profile which could be called with a prefixed view. If the operation was inherited, this would be illegal by the following rules; this rule puts inherited and noninherited routines on the same footing. Note that this only applies to tagged task types (that is, those with an interface in their declaration); we do that as there is no problem with prefixed view calls of primitive operations for “normal” task types, and having this rule apply to all tasks would be incompatible with Ada 95. 9.e/2

{AI95-00345-01} {AI95-00399-01} For each primitive subprogram inherited by the type declared by a task declaration, at most one of the following shall apply: 9.6/2

- {AI95-00345-01} the inherited subprogram is overridden with a primitive subprogram of the task type, in which case the overriding subprogram shall be subtype conformant with the inherited subprogram and not abstract; or 9.7/2
- {AI95-00345-01} {AI95-00397-01} the inherited subprogram is implemented by a single entry of the task type; in which case its prefixed view profile shall be subtype conformant with that of the task entry. 9.8/2

**Ramification:** An entry may implement two subprograms from the ancestors, one whose first parameter is of type `T` and one whose first parameter is of type `access T`. That doesn't cause implementation problems because “implemented by” (unlike “overridden”) probably entails the creation of wrappers. 9.f/2

If neither applies, the inherited subprogram shall be a null procedure. In addition to the places where Legality Rules normally apply (see 12.3), these rules also apply in the private part of an instance of a generic unit. 9.9/2

**Reason:** Each inherited subprogram can only have a single implementation (either from overriding a subprogram or implementing an entry), and must have an implementation unless the subprogram is a null procedure. 9.g/2

- 10 [ The elaboration of a task declaration elaborates the `task_definition`. The elaboration of a `single_task_declaration` also creates an object of an (anonymous) task type.]
- 10.a **Proof:** This is redundant with the general rules for the elaboration of a `full_type_declaration` and an `object_declaration`.
- 11 [The elaboration of a `task_definition` creates the task type and its first subtype;] it also includes the elaboration of the `entry_declarations` in the given order.
- 12/1 {8652/0009} {AI95-00137-01} As part of the initialization of a task object, any `aspect_clauses` and any per-object constraints associated with `entry_declarations` of the corresponding `task_definition` are elaborated in the given order.
- 12.a/1 **Reason:** The only `aspect_clauses` defined for task entries are ones that specify the Address of an entry, as part of defining an interrupt entry. These clearly need to be elaborated per-object, not per-type. Normally the address will be a function of a discriminant, if such an Address clause is in a task type rather than a single task declaration, though it could rely on a parameterless function that allocates sequential interrupt vectors.
- 12.b We do not mention representation pragmas, since each pragma may have its own elaboration rules.
- 13 The elaboration of a `task_body` has no effect other than to establish that tasks of the type can from then on be activated without failing the `Elaboration_Check`.
- 14 [The execution of a `task_body` is invoked by the activation of a task of the corresponding type (see 9.2).]
- 15 The content of a task object of a given task type includes:
- 16 • The values of the discriminants of the task object, if any;
- 17 • An entry queue for each entry of the task object;
- 17.a **Ramification:** "For each entry" implies one queue for each single entry, plus one for each entry of each entry family.
- 18 • A representation of the state of the associated task.
- NOTES
- 19/2 2 {AI95-00382-01} Other than in an `access_definition`, the name of a task unit within the declaration or body of the task unit denotes the current instance of the unit (see 8.6), rather than the first subtype of the corresponding task type (and thus the name cannot be used as a `subtype_mark`).
- 19.a/2 **Discussion:** {AI95-00382-01} It can be used as a `subtype_mark` in an anonymous access type. In addition, it is possible to refer to some other subtype of the task type within its body, presuming such a subtype has been declared between the `task_type_declaration` and the `task_body`.
- 20 3 The notation of a `selected_component` can be used to denote a discriminant of a task (see 4.1.3). Within a task unit, the name of a discriminant of the task type denotes the corresponding discriminant of the current instance of the unit.
- 21/2 4 {AI95-00287-01} A task type is a limited type (see 7.5), and hence precludes use of `assignment_statements` and predefined equality operators. If an application needs to store and exchange task identities, it can do so by defining an access type designating the corresponding task objects and by using access values for identification purposes. Assignment is available for such an access type as for any access type. Alternatively, if the implementation supports the Systems Programming Annex, the Identity attribute can be used for task identification (see C.7.1).

## Examples

- 22 *Examples of declarations of task types:*
- 23 `task type Server is`  
`entry Next_Work_Item(WI : in Work_Item);`  
`entry Shut_Down;`  
`end Server;`
- 24/2 {AI95-00433-01} `task type Keyboard_Driver(ID : Keyboard_ID := New_ID) is`  
`new Serial_Device with -- see 3.9.4`  
`entry Read (C : out Character);`  
`entry Write(C : in Character);`  
`end Keyboard_Driver;`

*Examples of declarations of single tasks:* 25

```

task Controller is 26
 entry Request(Level) (D : Item); -- a family of entries
end Controller;

task Parser is 27
 entry Next_Lexeme(L : in Lexical_Element);
 entry Next_Action(A : out Parser_Action);
end;

task User; -- has no entries 28

```

*Examples of task objects:* 29

```

Agent : Server; 30
Teletype : Keyboard_Driver(TTY_ID);
Pool : array(1 .. 10) of Keyboard_Driver;

```

*Example of access type designating task objects:* 31

```

type Keyboard is access Keyboard_Driver; 32
Terminal : Keyboard := new Keyboard_Driver(Term_ID);

```

*Extensions to Ada 83*

The syntax rules for task declarations are modified to allow a known\_discriminant\_part, and to allow a private part. They are also modified to allow entry\_declarations and aspect\_clauses to be mixed. 32.a/1

*Wording Changes from Ada 83*

The syntax rules for tasks have been split up according to task types and single tasks. In particular: The syntax rules for task\_declaration and task\_specification are removed. The syntax rules for task\_type\_declaration, single\_task\_declaration, task\_definition and task\_item are new. 32.b

The syntax rule for task\_body now uses the nonterminal handled\_sequence\_of\_statements. 32.c

The declarative\_part of a task\_body is now required; that doesn't make any real difference, because a declarative\_part can be empty. 32.d

*Extensions to Ada 95*

{AI95-00345-01} {AI95-00397-01} {AI95-00399-01} {AI95-00419-01} Task types and single tasks can be derived from one or more interfaces. Entries of the task type can implement the primitive operations of an interface. Overriding\_indicators can be used to specify whether or not an entry implements a primitive operation. 32.e/2

*Wording Changes from Ada 95*

{8652/0029} {AI95-00116-01} **Corrigendum:** Clarified that a task type has an implicit empty task\_definition if none is given. 32.f/2

{8652/0009} {AI95-00137-01} **Corrigendum:** Changed representation clauses to aspect clauses to reflect that they are used for more than just representation. 32.g/2

{AI95-00287-01} Revised the note on operations of task types to reflect that limited types do have an assignment operation, but not copying (assignment\_statements). 32.h/2

{AI95-00382-01} Revised the note on use of the name of a task type within itself to reflect the exception for anonymous access types. 32.i/2

*Extensions to Ada 2005*

{AI05-0183-1} {AI05-0267-1} An optional aspect\_specification can be used in a task\_type\_declaration, a single\_task\_declaration, and a task\_body. This is described in 13.1.1. 32.j/3

*Wording Changes from Ada 2005*

{AI05-0042-1} **Correction:** Clarified that an inherited procedure of a progenitor is overridden when it is implemented by an entry. 32.k/3

{AI05-0090-1} **Correction:** Added the missing defining name in the no conflicting primitive operation rule. 32.l/3

## 9.2 Task Execution - Task Activation

### *Dynamic Semantics*

- 1 The execution of a task of a given task type consists of the execution of the corresponding `task_body`. The initial part of this execution is called the *activation* of the task; it consists of the elaboration of the `declarative_part` of the `task_body`. Should an exception be propagated by the elaboration of its `declarative_part`, the activation of the task is defined to have *failed*, and it becomes a completed task.
- 2/2 *{AI95-00416-01}* A task object (which represents one task) can be a part of a stand-alone object, of an object created by an allocator, or of an anonymous object of a limited type, or a coextension of one of these. All tasks that are part or coextensions of any of the stand-alone objects created by the elaboration of `object_declarations` (or `generic_associations` of formal objects of mode **in**) of a single declarative region are activated together. All tasks that are part or coextensions of a single object that is not a stand-alone object are activated together.
- 2.a **Discussion:** The initialization of an `object_declaration` or allocator can indirectly include the creation of other objects that contain tasks. For example, the default expression for a subcomponent of an object created by an allocator might call a function that evaluates a completely different allocator. Tasks created by the two allocators are *not* activated together.
- 3/2 *{AI95-00416-01}* For the tasks of a given declarative region, the activations are initiated within the context of the `handled_sequence_of_statements` (and its associated `exception_handlers` if any — see 11.2), just prior to executing the statements of the `handled_sequence_of_statements`. [For a package without an explicit body or an explicit `handled_sequence_of_statements`, an implicit body or an implicit `null_statement` is assumed, as defined in 7.2.]
- 3.a **Ramification:** If `Tasking_Error` is raised, it can be handled by handlers of the `handled_sequence_of_statements`.
- 4/2 *{AI95-00416-01}* For tasks that are part or coextensions of a single object that is not a stand-alone object, activations are initiated after completing any initialization of the outermost object enclosing these tasks, prior to performing any other operation on the outermost object. In particular, for tasks that are part or coextensions of the object created by the evaluation of an allocator, the activations are initiated as the last step of evaluating the allocator, prior to returning the new access value. For tasks that are part or coextensions of an object that is the result of a function call, the activations are not initiated until after the function returns.
- 4.a/2 **Discussion:** *{AI95-00416-01}* The intent is that “temporary” objects with task parts (or coextensions) are treated similarly to an object created by an allocator. The “whole” object is initialized, and then all of the task parts (including the coextensions) are activated together. Each such “whole” object has its own task activation sequence, involving the activating task being suspended until all the new tasks complete their activation.
- 5 The task that created the new tasks and initiated their activations (the *activator*) is blocked until all of these activations complete (successfully or not). Once all of these activations are complete, if the activation of any of the tasks has failed [(due to the propagation of an exception)], `Tasking_Error` is raised in the activator, at the place at which it initiated the activations. Otherwise, the activator proceeds with its execution normally. Any tasks that are aborted prior to completing their activation are ignored when determining whether to raise `Tasking_Error`.
- 5.a **Ramification:** Note that a task created by an allocator does not necessarily depend on its activator; in such a case the activator's termination can precede the termination of the newly created task.
- 5.b **Discussion:** `Tasking_Error` is raised only once, even if two or more of the tasks being activated fail their activation.
- 5.c/2 **To be honest:** *{AI95-00265-01}* The pragma `Partition_Elaboration_Policy` (see H.6) can be used to defer task activation to a later point, thus changing many of these rules.
- 6/3 *{AI05-0045-1}* If the master that directly encloses the point where the activation of a task *T* would be initiated, completes before the activation of *T* is initiated, *T* becomes terminated and is never activated.

Furthermore, if a return statement is left such that the return object is not returned to the caller, any task that was created as a part of the return object or one of its coextensions immediately becomes terminated and is never activated.

**Ramification:** {AI05-0045-1} The first case can only happen if the activation point of T is not reached due to an exception being raised or a task or statement being aborted. Note that this is exclusive; if the master completes normally and starts finalization, we're already past the activation point. 6.a/3

{AI05-0045-1} The second case can happen with an exception being raised in a return statement, by an exit or goto from an `extended_return_statement`, or by a return statement being aborted. Any tasks created for the return object of such a return statement are never activated. 6.b/3

#### NOTES

5 An entry of a task can be called before the task has been activated. 7

6 If several tasks are activated together, the execution of any of these tasks need not await the end of the activation of the other tasks. 8

7 A task can become completed during its activation either because of an exception or because it is aborted (see 9.8). 9

#### Examples

*Example of task activation:*

```

procedure P is
 A, B : Server; -- elaborate the task objects A, B
 C : Server; -- elaborate the task object C
begin
 -- the tasks A, B, C are activated together before the first statement
 ...
end;

```

#### Wording Changes from Ada 83

We have replaced the term *suspended* with *blocked*, since we didn't want to consider a task blocked when it was simply competing for execution resources. "Suspended" is sometimes used more generally to refer to tasks that are not actually running on some processor, due to the lack of resources. 11.a

{AI05-0299-1} This subclause has been rewritten in an attempt to improve presentation. 11.b/3

#### Wording Changes from Ada 95

{AI95-00416-01} Adjusted the wording for activating tasks to handle the case of anonymous function return objects. This is critical; we don't want to be waiting for the tasks in a return object when we exit the function normally. 11.c/2

#### Wording Changes from Ada 2005

{AI05-0045-1} **Correction:** Corrected the wording that handles tasks that are never activated to ensure that no lookahead is implied and to make it clear that tasks created by return statements that never return are never activated. 11.d/3

## 9.3 Task Dependence - Termination of Tasks

#### Dynamic Semantics

Each task (other than an environment task — see 10.2) *depends* on one or more masters (see 7.6.1), as follows: 1

- If the task is created by the evaluation of an `allocator` for a given access type, it depends on each master that includes the elaboration of the declaration of the ultimate ancestor of the given access type. 2
- If the task is created by the elaboration of an `object_declaration`, it depends on each master that includes this elaboration. 3
- {AI95-00416-01} Otherwise, the task depends on the master of the outermost object of which it is a part (as determined by the accessibility level of that object — see 3.10.2 and 7.6.1), as well as on any master whose execution includes that of the master of the outermost object. 3.1/2

3.a/2 **Ramification:** {AI95-00416-01} The master of a task created by a return statement changes when the accessibility of the return object changes. Note that its activation happens, if at all, only after the function returns and all accessibility level changes have occurred.

4 Furthermore, if a task depends on a given master, it is defined to depend on the task that executes the master, and (recursively) on any master of that task.

4.a **Discussion:** Don't confuse these kinds of dependences with the dependences among compilation units defined in 10.1.1, "Compilation Units - Library Units".

5 A task is said to be *completed* when the execution of its corresponding `task_body` is completed. A task is said to be *terminated* when any finalization of the `task_body` has been performed (see 7.6.1). [The first step of finalizing a master (including a `task_body`) is to wait for the termination of any tasks dependent on the master.] The task executing the master is blocked until all the dependents have terminated. [Any remaining finalization is then performed and the master is left.]

6/1 Completion of a task (and the corresponding `task_body`) can occur when the task is blocked at a `select_`-statement with an open `terminate_alternative` (see 9.7.1); the open `terminate_alternative` is selected if and only if the following conditions are satisfied:

- 7/2 • {AI95-00415-01} The task depends on some completed master; and
- 8 • Each task that depends on the master considered is either already terminated or similarly blocked at a `select_statement` with an open `terminate_alternative`.

9 When both conditions are satisfied, the task considered becomes completed, together with all tasks that depend on the master considered that are not yet completed.

9.a **Ramification:** Any required finalization is performed after the selection of `terminate_alternatives`. The tasks are not callable during the finalization. In some ways it is as though they were aborted.

#### NOTES

10 8 The full view of a limited private type can be a task type, or can have subcomponents of a task type. Creation of an object of such a type creates dependences according to the full type.

11 9 An `object_renaming_declaration` defines a new view of an existing entity and hence creates no further dependence.

12 10 The rules given for the collective completion of a group of tasks all blocked on `select_statements` with open `terminate_alternatives` ensure that the collective completion can occur only when there are no remaining active tasks that could call one of the tasks being collectively completed.

13 11 If two or more tasks are blocked on `select_statements` with open `terminate_alternatives`, and become completed collectively, their finalization actions proceed concurrently.

14 12 The completion of a task can occur due to any of the following:

- 15 • the raising of an exception during the elaboration of the `declarative_part` of the corresponding `task_body`;
- 16 • the completion of the `handled_sequence_of_statements` of the corresponding `task_body`;
- 17 • the selection of an open `terminate_alternative` of a `select_statement` in the corresponding `task_body`;
- 18 • the abort of the task.

## Examples

Example of task dependence:

```

declare
 type Global is access Server; -- see 9.1
 A, B : Server;
 G : Global;
begin
 -- activation of A and B
 declare
 type Local is access Server;
 X : Global := new Server; -- activation of X.all
 L : Local := new Server; -- activation of L.all
 C : Server;
 begin
 -- activation of C
 G := X; -- both G and X designate the same task object
 ...
 end; -- await termination of C and L.all (but not X.all)
 ...
end; -- await termination of A, B, and G.all

```

19

20

## Wording Changes from Ada 83

We have revised the wording to be consistent with the definition of master now given in 7.6.1, “Completion and Finalization”. 20.a

Tasks that used to depend on library packages in Ada 83, now depend on the (implicit) `task_body` of the environment task (see 10.2). Therefore, the environment task has to wait for them before performing library level finalization and terminating the partition. In Ada 83 the requirement to wait for tasks that depended on library packages was not as clear. 20.b

What was “collective termination” is now “collective completion” resulting from selecting `terminate_alternatives`. This is because finalization still occurs for such tasks, and this happens after selecting the `terminate_alternative`, but before termination. 20.c

## Wording Changes from Ada 95

{AI95-00416-01} Added missing wording that explained the master of tasks that are neither object declarations nor allocators, such as function returns. 20.d/2

## 9.4 Protected Units and Protected Objects

A *protected object* provides coordinated access to shared data, through calls on its visible *protected operations*, which can be *protected subprograms* or *protected entries*. A *protected unit* is declared by a *protected declaration*, which has a corresponding `protected_body`. A protected declaration may be a `protected_type_declaration`, in which case it declares a named protected type; alternatively, it may be a `single_protected_declaration`, in which case it defines an anonymous protected type, as well as declaring a named protected object of that type. 1

## Syntax

```

{AI95-00345-01} {AI05-0183-1} protected_type_declaration ::=
protected type defining_identifier [known_discriminant_part]
 [aspect_specification] is
 [new interface_list with]
 protected_definition;

```

2/3

```

{AI95-00399-01} {AI05-0183-1} single_protected_declaration ::=
protected defining_identifier
 [aspect_specification] is
 [new interface_list with]
 protected_definition;

```

3/3

```

4 protected_definition ::=
 { protected_operation_declaration }
 [private
 { protected_element_declaration }]
 end [protected_identifier]
5/1 {8652/0009} {AI95-00137-01} protected_operation_declaration ::= subprogram_declaration
 | entry_declaration
 | aspect_clause
6 protected_element_declaration ::= protected_operation_declaration
 | component_declaration

```

6.a **Reason:** We allow the operations and components to be mixed because that's how other things work (for example, package declarations). We have relaxed the ordering rules for the items inside `declarative_parts` and `task_definitions` as well.

```

7/3 {AI05-0267-1} protected_body ::=
 protected body defining_identifier
 [aspect_specification] is
 { protected_operation_item }
 end [protected_identifier];

```

```

8/1 {8652/0009} {AI95-00137-01} protected_operation_item ::= subprogram_declaration
 | subprogram_body
 | entry_body
 | aspect_clause

```

9 If a *protected\_identifier* appears at the end of a `protected_definition` or `protected_body`, it shall repeat the *defining\_identifier*.

10.a/2 *This paragraph was deleted.*

*Paragraph 10 was deleted.*

#### Static Semantics

11/2 {AI95-00345-01} {AI95-00401-01} A `protected_definition` defines a protected type and its first subtype. The list of `protected_operation_declarations` of a `protected_definition`, together with the `known_discriminant_part`, if any, is called the visible part of the protected unit. [ The optional list of `protected_element_declarations` after the reserved word **private** is called the private part of the protected unit.]

11.a/3 **Proof:** {AI05-0299-1} Private part is defined in Clause 8.

11.1/3 {AI95-00345-01} {AI95-00397-01} {AI95-00399-01} {AI95-00419-01} {AI05-0042-1} For a protected declaration with an `interface_list`, the protected type inherits user-defined primitive subprograms from each progenitor type (see 3.9.4), in the same way that a derived type inherits user-defined primitive subprograms from its progenitor types (see 3.4). If the first parameter of a primitive inherited subprogram is of the protected type or an access parameter designating the protected type, and there is a `protected_operation_declaration` for a protected subprogram or single entry with the same identifier within the protected declaration, whose profile is type conformant with the prefixed view profile of the inherited subprogram, the inherited subprogram is said to be *implemented* by the conforming protected subprogram or entry using an implicitly declared nonabstract subprogram which has the same profile as the inherited subprogram and which overrides it.

11.b/2 **Ramification:** The inherited subprograms can only come from an interface given as part of the protected declaration.

11.b.1/3 **Reason:** {AI05-0042-1} The part about the implicitly declared subprogram is needed so that a subprogram implemented by an entry or subprogram is considered to be overridden for the purpose of the other rules of the language. Without it, it would for instance be illegal for an abstract subprogram to be implemented by an entry, because the abstract subprogram would not be overridden. The Legality Rules below ensure that there is no conflict between the implicit overriding subprogram and a user-defined overriding subprogram.

## Legality Rules

- {AI95-00345-01} A protected declaration requires a completion[, which shall be a `protected_body`,] and every `protected_body` shall be the completion of some protected declaration. 11.2/2
- To be honest:** {AI05-0229-1} If the implementation supports it, the protected body can be imported (using aspect `Import`, see B.1), in which case no explicit `protected_body` is allowed. 11.c/3
- {AI95-00345-01} {AI95-00399-01} [Each `interface_subtype_mark` of an `interface_list` appearing within a protected declaration shall denote a limited interface type that is not a task interface.] 11.3/2
- Proof:** 3.9.4 requires that an `interface_list` only name interface types, and limits the descendants of the various kinds of interface types. Only a limited, protected, or synchronized interface can have a protected type descendant. Nonlimited or task interfaces are not allowed, as they offer operations that a protected type does not have. 11.d/2
- {AI95-00397-01} {AI05-0042-1} The prefixed view profile of an explicitly declared primitive subprogram of a tagged protected type shall not be type conformant with any protected operation of the protected type, if the subprogram has the same defining name as the protected operation and the first parameter of the subprogram is of the protected type or is an access parameter designating the protected type. 11.4/3
- Reason:** This prevents the existence of two operations with the same name and profile which could be called with a prefixed view. If the operation was inherited, this would be illegal by the following rules; this rule puts inherited and noninherited routines on the same footing. Note that this only applies to tagged protected types (that is, those with an interface in their declaration); we do that as there is no problem with prefixed view calls of primitive operations for “normal” protected types, and having this rule apply to all protected types would be incompatible with Ada 95. 11.e/2
- {AI95-00345-01} {AI95-00399-01} For each primitive subprogram inherited by the type declared by a protected declaration, at most one of the following shall apply: 11.5/2
- {AI95-00345-01} the inherited subprogram is overridden with a primitive subprogram of the protected type, in which case the overriding subprogram shall be subtype conformant with the inherited subprogram and not abstract; or 11.6/2
  - {AI95-00345-01} {AI95-00397-01} the inherited subprogram is implemented by a protected subprogram or single entry of the protected type, in which case its prefixed view profile shall be subtype conformant with that of the protected subprogram or entry. 11.7/2
- If neither applies, the inherited subprogram shall be a null procedure. In addition to the places where Legality Rules normally apply (see 12.3), these rules also apply in the private part of an instance of a generic unit. 11.8/2
- Reason:** Each inherited subprogram can only have a single implementation (either from overriding a subprogram, implementing a subprogram, or implementing an entry), and must have an implementation unless the subprogram is a null procedure. 11.f/2
- {AI95-00345-01} {AI05-0291-1} If an inherited subprogram is implemented by a protected procedure or an entry, then the first parameter of the inherited subprogram shall be of mode **out** or **in out**, or an access-to-variable parameter. If an inherited subprogram is implemented by a protected function, then the first parameter of the inherited subprogram shall be of mode **in**, but not an access-to-variable parameter. 11.9/3
- Reason:** For a protected procedure or entry, the protected object can be read or written (see 9.5.1). A subprogram that is implemented by a protected procedure or entry must have a profile which reflects that in order to avoid confusion. Similarly, a protected function has a parameter that is a constant, and the inherited routine should reflect that. 11.g/3
- {AI95-00397-01} If a protected subprogram declaration has an `overriding_indicator`, then at the point of the declaration: 11.10/2
- if the `overriding_indicator` is **overriding**, then the subprogram shall implement an inherited subprogram; 11.11/2
  - if the `overriding_indicator` is **not overriding**, then the subprogram shall not implement any inherited subprogram. 11.12/2

11.13/2 In addition to the places where Legality Rules normally apply (see 12.3), these rules also apply in the private part of an instance of a generic unit.

11.h/2 **Discussion:** These rules are subtly different than those for subprograms (see 8.3.1) because there cannot be “late” inheritance of primitives from interfaces. Hidden (that is, private) interfaces are prohibited explicitly (see 7.3), as are hidden primitive operations (as private operations of public abstract types are prohibited — see 3.9.3).

*Dynamic Semantics*

12 [The elaboration of a protected declaration elaborates the `protected_definition`. The elaboration of a `single_protected_declaration` also creates an object of an (anonymous) protected type.]

12.a **Proof:** This is redundant with the general rules for the elaboration of a `full_type_declaration` and an `object_declaration`.

13 [The elaboration of a `protected_definition` creates the protected type and its first subtype;] it also includes the elaboration of the `component_declarations` and `protected_operation_declarations` in the given order.

14 [As part of the initialization of a protected object, any per-object constraints (see 3.8) are elaborated.]

14.a **Discussion:** We do not mention pragmas since each pragma has its own elaboration rules.

15 The elaboration of a `protected_body` has no other effect than to establish that protected operations of the type can from then on be called without failing the `Elaboration_Check`.

16 The content of an object of a given protected type includes:

- 17 • The values of the components of the protected object, including (implicitly) an entry queue for each entry declared for the protected object;

17.a **Ramification:** "For each entry" implies one queue for each single entry, plus one for each entry of each entry family.

- 18 • A representation of the state of the execution resource *associated* with the protected object (one such resource is associated with each protected object).

19 [The execution resource associated with a protected object has to be acquired to read or update any components of the protected object; it can be acquired (as part of a protected action — see 9.5.1) either for concurrent read-only access, or for exclusive read-write access.]

20 As the first step of the *finalization* of a protected object, each call remaining on any entry queue of the object is removed from its queue and `Program_Error` is raised at the place of the corresponding `entry_-call_statement`.

20.a **Reason:** This is analogous to the raising of `Tasking_Error` in callers of a task that completes before accepting the calls. This situation can only occur due to a requeue (ignoring premature `unchecked_deallocation`), since any task that has accessibility to a protected object is awaited before finalizing the protected object. For example:

```
20.b procedure Main is
 task T is
 entry E;
 end T;
20.c task body T is
 protected PO is
 entry Ee;
 end PO;
```

```

 protected body PO is
 entry Ee when False is
 begin
 null;
 end Ee;
 end PO;
 begin
 accept E do
 requeue PO.Ee;
 end E;
 end T;
begin
 T.E;
end Main;

```

{AI05-0005-1} The environment task is queued on PO.Ee when PO is finalized. 20.d  
20.e/3

In a real example, a server task might park callers on a local protected object for some useful purpose, so we didn't want to disallow this case. 20.f

#### Bounded (Run-Time) Errors

{AI95-00280-01} It is a bounded error to call an entry or subprogram of a protected object after that object is finalized. If the error is detected, Program\_Error is raised. Otherwise, the call proceeds normally, which may leave a task queued forever. 20.1/2

**Reason:** This is very similar to the finalization rule. It is a bounded error so that an implementation can avoid the overhead of the check if it can ensure that the call still will operate properly. Such an implementation cannot need to return resources (such as locks) to an executive that it needs to execute calls. 20.g/2

This case can happen (and has happened in production code) when a protected object is accessed from the Finalize routine of a type. For example: 20.h/2

```

with Ada.Finalization.Controlled;
package Window_Manager is
 ...
 type Root_Window is new Ada.Finalization.Controlled with private;
 type Any_Window is access all Root_Window;
 ...
private
 ...
 procedure Finalize (Object : in out Root_Window);
 ...
end Window_Manager;
package body Window_Manager is
 protected type Lock is
 entry Get_Lock;
 procedure Free_Lock;
 ...
 end Lock;
 Window_Lock : Lock;
 procedure Finalize (Object : in out Root_Window) is
 begin
 Window_Lock.Get_Lock;
 ...
 Window_Lock.Free_Lock;
 end Finalize;
 ...
 A_Window : Any_Window := new Root_Window;
end Window_Manager;

```

The environment task will call Window\_Lock for the object allocated for A\_Window when the collection for Any\_Window is finalized, which will happen after the finalization of Window\_Lock (because finalization of the package body will occur before that of the package specification). 20.i/2  
20.k/2  
20.l/2

#### NOTES

13 {AI95-00382-01} Within the declaration or body of a protected unit other than in an access\_definition, the name of the protected unit denotes the current instance of the unit (see 8.6), rather than the first subtype of the corresponding protected type (and thus the name cannot be used as a subtype\_mark). 21/2

**Discussion:** {AI95-00382-01} It can be used as a subtype\_mark in an anonymous access type. In addition, it is possible to refer to some other subtype of the protected type within its body, presuming such a subtype has been declared between the protected\_type\_declaration and the protected\_body. 21.a/2

- 22 14 A `selected_component` can be used to denote a discriminant of a protected object (see 4.1.3). Within a protected unit, the name of a discriminant of the protected type denotes the corresponding discriminant of the current instance of the unit.
- 23/2 15 {AI95-00287-01} A protected type is a limited type (see 7.5), and hence precludes use of `assignment_statements` and predefined equality operators.
- 24 16 The bodies of the protected operations given in the `protected_body` define the actions that take place upon calls to the protected operations.
- 25 17 The declarations in the private part are only visible within the private part and the body of the protected unit.
- 25.a **Reason:** `Component_declarations` are disallowed in a `protected_body` because, for efficiency, we wish to allow the compiler to determine the size of protected objects (when not dynamic); the compiler cannot necessarily see the body. Furthermore, the semantics of initialization of such objects would be problematic — we do not wish to give protected objects complex initialization semantics similar to task activation.
- 25.b The same applies to `entry_declarations`, since an entry involves an implicit component — the entry queue.

*Examples*

26 *Example of declaration of protected type and corresponding body:*

```

27 protected type Resource is
 entry Seize;
 procedure Release;
private
 Busy : Boolean := False;
end Resource;

28 protected body Resource is
 entry Seize when not Busy is
 begin
 Busy := True;
 end Seize;

29 procedure Release is
 begin
 Busy := False;
 end Release;
end Resource;
```

30 *Example of a single protected declaration and corresponding body:*

```

31 protected Shared_Array is
 -- Index, Item, and Item_Array are global types
 function Component (N : in Index) return Item;
 procedure Set_Component (N : in Index; E : in Item);
private
 Table : Item_Array(Index) := (others => Null_Item);
end Shared_Array;

32 protected body Shared_Array is
 function Component (N : in Index) return Item is
 begin
 return Table(N);
 end Component;

33 procedure Set_Component (N : in Index; E : in Item) is
 begin
 Table(N) := E;
 end Set_Component;
end Shared_Array;
```

34 *Examples of protected objects:*

```

35 Control : Resource;
 Flags : array(1 .. 100) of Resource;
```

*Extensions to Ada 83*

- 35.a/3 {AI05-0299-1} This entire subclause is new; protected units do not exist in Ada 83.

*Extensions to Ada 95*

{AI95-00345-01} {AI95-00397-01} {AI95-00399-01} {AI95-00401-01} {AI95-00419-01} Protected types and single protected objects can be derived from one or more interfaces. Operations declared in the protected type can implement the primitive operations of an interface. `Overriding_indicators` can be used to specify whether or not a protected operation implements a primitive operation. 35.b/2

*Wording Changes from Ada 95*

{8652/0009} {AI95-00137-01} **Corrigendum:** Changed representation clauses to aspect clauses to reflect that they are used for more than just representation. 35.c/2

{AI95-00280-01} Described what happens when an operation of a finalized protected object is called. 35.d/2

{AI95-00287-01} Revised the note on operations of protected types to reflect that limited types do have an assignment operation, but not copying (`assignment_statements`). 35.e/2

{AI95-00382-01} Revised the note on use of the name of a protected type within itself to reflect the exception for anonymous access types. 35.f/2

*Incompatibilities With Ada 2005*

{AI05-0291-1} When an inherited subprogram is implemented by a protected function, the first parameter has to be an **in** parameter, but not an access-to-variable type. Ada 2005 allowed access-to-variable parameters in this case; the parameter will need to be changed to access-to-constant with the addition of the **constant** keyword. 35.g/3

*Extensions to Ada 2005*

{AI05-0183-1} {AI05-0267-1} An optional `aspect_specification` can be used in a `protected_type_declaration`, a `single_protected_declaration`, and a `protected_body`. This is described in 13.1.1. 35.h/3

*Wording Changes from Ada 2005*

{AI05-0042-1} **Correction:** Clarified that an inherited subprogram of a progenitor is overridden when it is implemented by an entry or subprogram. 35.i/3

{AI05-0090-1} **Correction:** Added the missing defining name in the no conflicting primitive operation rule. 35.j/3

## 9.5 Intertask Communication

The primary means for intertask communication is provided by calls on entries and protected subprograms. Calls on protected subprograms allow coordinated access to shared data objects. Entry calls allow for blocking the caller until a given condition is satisfied (namely, that the corresponding entry is open — see 9.5.3), and then communicating data or control information directly with another task or indirectly via a shared protected object. 1

*Static Semantics*

{AI05-0225-1} {AI05-0291-1} When a **name** or **prefix** denotes an entry, protected subprogram, or a prefixed view of a primitive subprogram of a limited interface whose first parameter is a controlling parameter, the **name** or **prefix** determines a *target object*, as follows: 2/3

**To be honest:** {AI05-0291-1} This wording uses "denotes" to mean "denotes a view of an entity" (when the term is used in Legality Rules), and "denotes an entity" (when the term is used in Dynamic Semantics rules). It does not mean "view of a declaration", as that would not include renames (a renames is not an entry or protected subprogram). 2.a/3

- {AI05-0291-1} If it is a `direct_name` or expanded name that denotes the declaration (or body) of the operation, then the target object is implicitly specified to be the current instance of the task or protected unit immediately enclosing the operation; a call using such a name is defined to be an *internal call*; 3/3
- {AI05-0291-1} If it is a `selected_component` that is not an expanded name, then the target object is explicitly specified to be the object denoted by the prefix of the name; a call using such a name is defined to be an *external call*; 4/3

**Discussion:** For example: 4.a

```

4.b protected type Pt is
 procedure Op1;
 procedure Op2;
 end Pt;
4.c PO : Pt;
 Other_Object : Some_Other_Protected_Type;
4.d protected body Pt is
 procedure Op1 is begin ... end Op1;
4.e procedure Op2 is
 begin
 Op1; -- An internal call.
 Pt.Op1; -- Another internal call.
 PO.Op1; -- An external call. If the current instance is PO, then
 -- this is a bounded error (see 9.5.1).
 Other_Object.Some_Op; -- An external call.
 end Op2;
 end Pt;

```

- 5/3 • *{AI05-0291-1}* If the name or prefix is a dereference (implicit or explicit) of an access-to-protected-subprogram value, then the target object is determined by the prefix of the Access attribute\_reference that produced the access value originally; a call using such a name is defined to be an *external call*;
- 6 • If the name or prefix denotes a subprogram\_renaming\_declaration, then the target object is as determined by the name of the renamed entity.
- 6.1/3 *{AI05-0291-1}* A call on an entry or a protected subprogram either uses a name or prefix that determines a target object implicitly, as above, or is a call on (a non-prefixed view of) a primitive subprogram of a limited interface whose first parameter is a controlling parameter, in which case the target object is identified explicitly by the first parameter. This latter case is an *external call*.
- 7 A corresponding definition of target object applies to a *requeue\_statement* (see 9.5.4), with a corresponding distinction between an *internal requeue* and an *external requeue*.

#### Legality Rules

- 7.1/3 *{AI95-00345-01}* *{AI05-0225-1}* *{AI05-0291-1}* If a name or prefix determines a target object, and the name denotes a protected entry or procedure, then the target object shall be a variable, unless the prefix is for an attribute\_reference to the Count attribute (see 9.9).
- 7.a/3 **Reason:** *{AI05-0225-1}* The point is to prevent any calls to such a name whose target object is a constant view of a protected object, directly, or via an access value, renames, or generic formal subprogram. It is, however, legal to say P'Count in a protected function body, even though the protected object is a constant view there.
- 7.b/3 **Ramification:** *{AI05-0291-1}* This rule does not apply to calls that are not to a prefixed view. Specifically a "normal" call to a primitive operation of a limited interface is not covered by this rule. In that case, the normal parameter passing mode checks will prevent passing a constant protected object to an operation implemented by a protected entry or procedure as the mode is required to be **in out** or **out**.

#### Dynamic Semantics

- 8 Within the body of a protected operation, the current instance (see 8.6) of the immediately enclosing protected unit is determined by the target object specified (implicitly or explicitly) in the call (or requeue) on the protected operation.
- 8.a **To be honest:** The current instance is defined in the same way within the body of a subprogram declared immediately within a protected\_body.
- 9 Any call on a protected procedure or entry of a target protected object is defined to be an update to the object, as is a requeue on such an entry.
- 9.a **Reason:** Read/write access to the components of a protected object is granted while inside the body of a protected procedure or entry. Also, any protected entry call can change the value of the Count attribute, which represents an update. Any protected procedure call can result in servicing the entries, which again might change the value of a Count attribute.

*Syntax*

{AI05-0030-2} {AI05-0215-1} `synchronization_kind ::=` 10/3  
`By_Entry | By_Protected_Procedure | Optional`

*Static Semantics*

{AI05-0215-1} For the declaration of a primitive procedure of a synchronized tagged type the following language-defined representation aspect may be specified with an `aspect_specification` (see 13.1.1): 11/3

Synchronization 12/3

If specified, the aspect definition shall be a `synchronization_kind`.

**Aspect Description for Synchronization:** Defines whether a given primitive operation of a synchronized interface must be implemented by an entry or protected procedure. 12.a/3

{AI05-0030-2} {AI05-0215-1} Inherited subprograms inherit the Synchronization aspect, if any, from the corresponding subprogram of the parent or progenitor type. If an overriding operation does not have a directly specified Synchronization aspect then the Synchronization aspect of the inherited operation is inherited by the overriding operation. 13/3

*Legality Rules*

{AI05-0030-2} {AI05-0215-1} The `synchronization_kind` `By_Protected_Procedure` shall not be applied to a primitive procedure of a task interface. 14/3

{AI05-0030-2} {AI05-0215-1} A procedure for which the specified `synchronization_kind` is `By_Entry` shall be implemented by an entry. A procedure for which the specified `synchronization_kind` is `By_Protected_Procedure` shall be implemented by a protected procedure. A procedure for which the specified `synchronization_kind` is `Optional` may be implemented by an entry or by a procedure (including a protected procedure). 15/3

{AI05-0030-2} {AI05-0215-1} If a primitive procedure overrides an inherited operation for which the Synchronization aspect has been specified to be `By_Entry` or `By_Protected_Procedure`, then any specification of the aspect Synchronization applied to the overriding operation shall have the same `synchronization_kind`. 16/3

{AI05-0030-2} In addition to the places where Legality Rules normally apply (see 12.3), these rules also apply in the private part of an instance of a generic unit. 17/3

## NOTES

18 {AI05-0030-2} {AI05-0215-1} The `synchronization_kind` `By_Protected_Procedure` implies that the operation will not block. 18/3

*Wording Changes from Ada 95*

{AI95-00345-01} Added a Legality Rule to make it crystal-clear that the protected object of an entry or procedure call must be a variable. This rule was implied by the Dynamic Semantics here, along with the Static Semantics of 3.3, but it is much better to explicitly say it. While many implementations have gotten this wrong, this is not an incompatibility — allowing updates of protected constants has always been wrong. 18.a/2

*Extensions to Ada 2005*

{AI05-0030-2} {AI05-0215-1} Added the Synchronization aspect to allow specifying that an interface procedure is really an entry or a protected procedure. 18.b/3

*Wording Changes from Ada 2005*

{AI05-0225-1} **Correction:** Clarified that the target object of any name denoted a protected procedure or entry can never be a constant (other than for the 'Count attribute). This closes holes involving calls to `access-to-protected`, renaming as a procedure, and generic formal subprograms. 18.c/3

## 9.5.1 Protected Subprograms and Protected Actions

1 A *protected subprogram* is a subprogram declared immediately within a `protected_definition`. Protected procedures provide exclusive read-write access to the data of a protected object; protected functions provide concurrent read-only access to the data.

1.a **Ramification:** A subprogram declared immediately within a `protected_body` is not a protected subprogram; it is an intrinsic subprogram. See 6.3.1, “Conformance Rules”.

### Static Semantics

2 [Within the body of a protected function (or a function declared immediately within a `protected_body`), the current instance of the enclosing protected unit is defined to be a constant (that is, its subcomponents may be read but not updated). Within the body of a protected procedure (or a procedure declared immediately within a `protected_body`), and within an `entry_body`, the current instance is defined to be a variable (updating is permitted).]

2.a.1/3 **Proof:** {AI05-0120-1} All constant views are defined in 3.3, “Objects and Named Numbers”, anything not named there is a variable view.

2.a **Ramification:** The current instance is like an implicit parameter, of mode `in` for a protected function, and of mode `in out` for a protected procedure (or protected entry).

### Dynamic Semantics

3 For the execution of a call on a protected subprogram, the evaluation of the `name` or `prefix` and of the parameter associations, and any assigning back of `in out` or `out` parameters, proceeds as for a normal subprogram call (see 6.4). If the call is an internal call (see 9.5), the body of the subprogram is executed as for a normal subprogram call. If the call is an external call, then the body of the subprogram is executed as part of a new *protected action* on the target protected object; the protected action completes after the body of the subprogram is executed. [A protected action can also be started by an entry call (see 9.5.3).]

4 A new protected action is not started on a protected object while another protected action on the same protected object is underway, unless both actions are the result of a call on a protected function. This rule is expressible in terms of the execution resource associated with the protected object:

5 • *Starting* a protected action on a protected object corresponds to *acquiring* the execution resource associated with the protected object, either for concurrent read-only access if the protected action is for a call on a protected function, or for exclusive read-write access otherwise;

6 • *Completing* the protected action corresponds to *releasing* the associated execution resource.

7 [After performing an operation on a protected object other than a call on a protected function, but prior to completing the associated protected action, the entry queues (if any) of the protected object are serviced (see 9.5.3).]

### Bounded (Run-Time) Errors

8 During a protected action, it is a bounded error to invoke an operation that is *potentially blocking*. The following are defined to be potentially blocking operations:

8.a **Reason:** Some of these operations are not directly blocking. However, they are still treated as bounded errors during a protected action, because allowing them might impose an undesirable implementation burden.

9 • a `select_statement`;

10 • an `accept_statement`;

11 • an `entry_call_statement`;

- a `delay_statement`; 12
  - an `abort_statement`; 13
  - task creation or activation; 14
  - an external call on a protected subprogram (or an external requeue) with the same target object as that of the protected action; 15
    - Reason:** This is really a deadlocking call, rather than a blocking call, but we include it in this list for simplicity. 15.a
  - a call on a subprogram whose body contains a potentially blocking operation. 16
    - Reason:** This allows an implementation to check and raise `Program_Error` as soon as a subprogram is called, rather than waiting to find out whether it actually reaches the potentially blocking operation. This in turn allows the potentially blocking operation check to be performed prior to run time in some environments. 16.a
- If the bounded error is detected, `Program_Error` is raised. If not detected, the bounded error might result in deadlock or a (nested) protected action on the same target object. 17
- Discussion:** *{AI95-00305-01}* By “nested protected action”, we mean that an additional protected action can be started by another task on the same protected object. This means that mutual exclusion may be broken in this bounded error case. A way to ensure that this does not happen is to use `pragma Detect_Blocking` (see H.5). 17.a/2
- Certain language-defined subprograms are potentially blocking. In particular, the subprograms of the language-defined input-output packages that manipulate files (implicitly or explicitly) are potentially blocking. Other potentially blocking subprograms are identified where they are defined. When not specified as potentially blocking, a language-defined subprogram is nonblocking. 18
- Discussion:** *{AI95-00178-01}* Any subprogram in a language-defined input-output package that has a file parameter or result or operates on a default file is considered to manipulate a file. An instance of a language-defined input-output generic package provides subprograms that are covered by this rule. The only subprograms in language-defined input-output packages not covered by this rule (and thus not potentially blocking) are the `Get` and `Put` routines that take string parameters defined in the packages nested in `Text_IO`. 18.a/2
- NOTES
- 19 If two tasks both try to start a protected action on a protected object, and at most one is calling a protected function, then only one of the tasks can proceed. Although the other task cannot proceed, it is not considered blocked, and it might be consuming processing resources while it awaits its turn. There is no language-defined ordering or queuing presumed for tasks competing to start a protected action — on a multiprocessor such tasks might use busy-waiting; for monoprocessor considerations, see D.3, “Priority Ceiling Locking”. 19
- Discussion:** The intended implementation on a multi-processor is in terms of “spin locks” — the waiting task will spin. 19.a
- 20 The body of a protected unit may contain declarations and bodies for local subprograms. These are not visible outside the protected unit. 20
- 21 The body of a protected function can contain internal calls on other protected functions, but not protected procedures, because the current instance is a constant. On the other hand, the body of a protected procedure can contain internal calls on both protected functions and procedures. 21
- 22 From within a protected action, an internal call on a protected subprogram, or an external call on a protected subprogram with a different target object is not considered a potentially blocking operation. 22
- Reason:** This is because a task is not considered blocked while attempting to acquire the execution resource associated with a protected object. The acquisition of such a resource is rather considered part of the normal competition for execution resources between the various tasks that are ready. External calls that turn out to be on the same target object are considered potentially blocking, since they can deadlock the task indefinitely. 22.a
- 23 *{AI95-00305-01}* The `pragma Detect_Blocking` may be used to ensure that all executions of potentially blocking operations during a protected action raise `Program_Error`. See H.5. 22.1/2

#### *Examples*

- Examples of protected subprogram calls (see 9.4):* 23
- ```

Shared_Array.Set_Component (N, E);
E := Shared_Array.Component (M);
Control.Release;
  
```
- 24

- 24.a/2 *{AI95-00305-01}* Added a note pointing out the existence of `pragma Detect_Blocking`. This pragma can be used to ensure portable (somewhat pessimistic) behavior of protected actions by converting the Bounded Error into a required check.

9.5.2 Entries and Accept Statements

- 1 Entry_declarations, with the corresponding entry_bodies or accept_statements, are used to define potentially queued operations on tasks and protected objects.

Syntax

- 2/3 *{AI95-00397-01}* *{AI05-0183-1}* entry_declaration ::=
 [overriding_indicator]
entry defining_identifier [(discrete_subtype_definition)] parameter_profile
 [aspect_specification];
- 3 accept_statement ::=
accept entry_direct_name [(entry_index)] parameter_profile [**do**
 handled_sequence_of_statements
end [entry_identifier]];
- 3.a **Reason:** We cannot use defining_identifier for accept_statements. Although an accept_statement is sort of like a body, it can appear nested within a block_statement, and therefore be hidden from its own entry by an outer homograph.
- 4 entry_index ::= expression
- 5 entry_body ::=
entry defining_identifier entry_body_formal_part entry_barrier **is**
 declarative_part
begin
 handled_sequence_of_statements
end [entry_identifier];
- 5.a/2 **Discussion:** *{AI95-00397-01}* We don't allow an overriding_indicator on an entry_body because entries always implement procedures at the point of the type declaration; there is no late implementation. And we don't want to have to think about overriding_indicators on accept_statements.
- 6 entry_body_formal_part ::= [(entry_index_specification)] parameter_profile
- 7 entry_barrier ::= **when** condition
- 8 entry_index_specification ::= **for** defining_identifier **in** discrete_subtype_definition
- 9 If an entry_identifier appears at the end of an accept_statement, it shall repeat the entry_direct_name. If an entry_identifier appears at the end of an entry_body, it shall repeat the defining_identifier.
- 10 [An entry_declaration is allowed only in a protected or task declaration.]
- 10.a **Proof:** This follows from the BNF.
- 10.1/2 *{AI95-00397-01}* An overriding_indicator is not allowed in an entry_declaration that includes a discrete_subtype_definition.
- 10.a.1/2 **Reason:** An entry family can never implement something, so allowing an indicator is felt by the majority of the ARG to be redundant.

Name Resolution Rules

- 11 In an accept_statement, the expected profile for the entry_direct_name is that of the entry_declaration; the expected type for an entry_index is that of the subtype defined by the discrete_subtype_definition of the corresponding entry_declaration.

Within the `handled_sequence_of_statements` of an `accept_statement`, if a `selected_component` has a prefix that denotes the corresponding `entry_declaration`, then the entity denoted by the prefix is the `accept_statement`, and the `selected_component` is interpreted as an expanded name (see 4.1.3); the `selector_name` of the `selected_component` has to be the identifier for some formal parameter of the `accept_statement`]. 12

Proof: The only declarations that occur immediately within the declarative region of an `accept_statement` are those for its formal parameters. 12.a

Legality Rules

An `entry_declaration` in a task declaration shall not contain a specification for an access parameter (see 3.10). 13

Reason: Access parameters for task entries would require a complex implementation. For example: 13.a

```

task T is
  entry E(Z : access Integer); -- Illegal!
end T;
task body T is
begin
  declare
    type A is access all Integer;
    X : A;
    Int : aliased Integer;
    task Inner;
    task body Inner is
    begin
      T.E(Int'Access);
    end Inner;
  begin
    accept E(Z : access Integer) do
      X := A(Z); -- Accessibility_Check
    end E;
  end;
end T;

```

13.b
13.c

Implementing the `Accessibility_Check` inside the `accept_statement` for `E` is difficult, since one does not know whether the entry caller is calling from inside the immediately enclosing `declare` block or from outside it. This means that the lexical nesting level associated with the designated object is not sufficient to determine whether the `Accessibility_Check` should pass or fail. 13.d

Note that such problems do not arise with protected entries, because `entry_bodies` are always nested immediately within the `protected_body`; they cannot be further nested as can `accept_statements`, nor can they be called from within the `protected_body` (since no entry calls are permitted inside a `protected_body`). 13.e

{AI95-00397-01} If an `entry_declaration` has an `overriding_indicator`, then at the point of the declaration: 13.1/2

- if the `overriding_indicator` is **overriding**, then the entry shall implement an inherited subprogram; 13.2/2
- if the `overriding_indicator` is **not overriding**, then the entry shall not implement any inherited subprogram. 13.3/2

In addition to the places where Legality Rules normally apply (see 12.3), these rules also apply in the private part of an instance of a generic unit. 13.4/2

Discussion: These rules are subtly different than those for subprograms (see 8.3.1) because there cannot be “late” inheritance of primitives from interfaces. Hidden (that is, private) interfaces are prohibited explicitly (see 7.3), as are hidden primitive operations (as private operations of public abstract types are prohibited — see 3.9.3). 13.1/2

For an `accept_statement`, the innermost enclosing body shall be a `task_body`, and the `entry_direct_name` shall denote an `entry_declaration` in the corresponding task declaration; the profile of the `accept_statement` shall conform fully to that of the corresponding `entry_declaration`. An `accept_statement` shall have a parenthesized `entry_index` if and only if the corresponding `entry_declaration` has a `discrete_subtype_definition`. 14

- 15 An `accept_statement` shall not be within another `accept_statement` that corresponds to the same `entry_declaration`, nor within an `asynchronous_select` inner to the enclosing `task_body`.
- 15.a **Reason:** `Accept_statements` are required to be immediately within the enclosing `task_body` (as opposed to being in a nested subprogram) to ensure that a nested task does not attempt to accept the entry of its enclosing task. We considered relaxing this restriction, either by making the check a run-time check, or by allowing a nested task to accept an entry of its enclosing task. However, neither change seemed to provide sufficient benefit to justify the additional implementation burden.
- 15.b Nested `accept_statements` for the same entry (or entry family) are prohibited to ensure that there is no ambiguity in the resolution of an expanded name for a formal parameter of the entry. This could be relaxed by allowing the inner one to hide the outer one from all visibility, but again the small added benefit didn't seem to justify making the change for Ada 95.
- 15.c `Accept_statements` are not permitted within `asynchronous_select` statements to simplify the semantics and implementation: an `accept_statement` in an `abortable_part` could result in `Tasking_Error` being propagated from an entry call even though the target task was still callable; implementations that use multiple tasks implicitly to implement an `asynchronous_select` might have trouble supporting "up-level" accepts. Furthermore, if `accept_statements` were permitted in the `abortable_part`, a task could call its own entry and then accept it in the `abortable_part`, leading to rather unusual and possibly difficult-to-specify semantics.
- 16 An `entry_declaration` of a protected unit requires a completion[, which shall be an `entry_body`,] and every `entry_body` shall be the completion of an `entry_declaration` of a protected unit. The profile of the `entry_body` shall conform fully to that of the corresponding declaration.
- 16.a **Ramification:** An `entry_declaration`, unlike a `subprogram_declaration`, cannot be completed with a `renaming_declaration`.
- 16.b/3 **To be honest:** *{AI05-0229-1}* If the implementation supports it, the entry body can be imported (using aspect `Import`, see B.1), in which case no explicit `entry_body` is allowed.
- 16.c **Discussion:** The above applies only to protected entries, which are the only ones completed with `entry_bodies`. Task entries have corresponding `accept_statements` instead of having `entry_bodies`, and we do not consider an `accept_statement` to be a "completion," because a task `entry_declaration` is allowed to have zero, one, or more than one corresponding `accept_statements`.
- 17 An `entry_body_formal_part` shall have an `entry_index_specification` if and only if the corresponding `entry_declaration` has a `discrete_subtype_definition`. In this case, the `discrete_subtype_definitions` of the `entry_declaration` and the `entry_index_specification` shall fully conform to one another (see 6.3.1).
- 18 A name that denotes a formal parameter of an `entry_body` is not allowed within the `entry_barrier` of the `entry_body`.

Static Semantics

- 19 The parameter modes defined for parameters in the `parameter_profile` of an `entry_declaration` are the same as for a `subprogram_declaration` and have the same meaning (see 6.2).
- 19.a **Discussion:** Note that access parameters are not allowed for task entries (see above).
- 20 An `entry_declaration` with a `discrete_subtype_definition` (see 3.6) declares a *family* of distinct entries having the same profile, with one such entry for each value of the *entry index subtype* defined by the `discrete_subtype_definition`. [A name for an entry of a family takes the form of an `indexed_component`, where the prefix denotes the `entry_declaration` for the family, and the index value identifies the entry within the family.] The term *single entry* is used to refer to any entry other than an entry of an entry family.
- 21 In the `entry_body` for an entry family, the `entry_index_specification` declares a named constant whose subtype is the entry index subtype defined by the corresponding `entry_declaration`; the value of the *named entry index* identifies which entry of the family was called.
- 21.a **Ramification:** The `discrete_subtype_definition` of the `entry_index_specification` is not elaborated; the subtype of the named constant declared is defined by the `discrete_subtype_definition` of the corresponding `entry_declaration`, which is elaborated, either when the type is declared, or when the object is created, if its constraint is per-object.

Dynamic Semantics

- {8652/0002} {AI95-00171-01} The elaboration of an `entry_declaration` for an entry family consists of the elaboration of the `discrete_subtype_definition`, as described in 3.8. The elaboration of an `entry_declaration` for a single entry has no effect. 22/1
- Discussion:** {AI05-0299-1} The elaboration of the declaration of a protected subprogram has no effect, as specified in subclause 6.1. The default initialization of an object of a task or protected type is covered in 3.3.1. 22.a/3
- [The actions to be performed when an entry is called are specified by the corresponding `accept_statements` (if any) for an entry of a task unit, and by the corresponding `entry_body` for an entry of a protected unit.] 23
- For the execution of an `accept_statement`, the `entry_index`, if any, is first evaluated and converted to the entry index subtype; this index value identifies which entry of the family is to be accepted. Further execution of the `accept_statement` is then blocked until a caller of the corresponding entry is selected (see 9.5.3), whereupon the `handled_sequence_of_statements`, if any, of the `accept_statement` is executed, with the formal parameters associated with the corresponding actual parameters of the selected entry call. Upon completion of the `handled_sequence_of_statements`, the `accept_statement` completes and is left. When an exception is propagated from the `handled_sequence_of_statements` of an `accept_statement`, the same exception is also raised by the execution of the corresponding `entry_call_statement`. 24
- Ramification:** This is in addition to propagating it to the construct containing the `accept_statement`. In other words, for a rendezvous, the raising splits in two, and continues concurrently in both tasks. 24.a
- The caller gets a new occurrence; this isn't considered propagation. 24.b
- Note that we say “propagated from the `handled_sequence_of_statements` of an `accept_statement`”, not “propagated from an `accept_statement`.” The latter would be wrong — we don't want exceptions propagated by the `entry_index` to be sent to the caller (there is none yet!). 24.c
- The above interaction between a calling task and an accepting task is called a *rendezvous*. [After a rendezvous, the two tasks continue their execution independently.] 25
- [An `entry_body` is executed when the condition of the `entry_barrier` evaluates to True and a caller of the corresponding single entry, or entry of the corresponding entry family, has been selected (see 9.5.3).] For the execution of the `entry_body`, the `declarative_part` of the `entry_body` is elaborated, and the `handled_sequence_of_statements` of the body is executed, as for the execution of a `subprogram_body`. The value of the named entry index, if any, is determined by the value of the entry index specified in the `entry_name` of the selected entry call (or intermediate `requeue_statement` — see 9.5.4). 26
- To be honest:** If the entry had been renamed as a subprogram, and the call was a `procedure_call_statement` using the name declared by the renaming, the entry index (if any) comes from the entry name specified in the `subprogram_renaming_declaration`. 26.a
- NOTES
- 24 A task entry has corresponding `accept_statements` (zero or more), whereas a protected entry has a corresponding `entry_body` (exactly one). 27
- 25 A consequence of the rule regarding the allowed placements of `accept_statements` is that a task can execute `accept_statements` only for its own entries. 28
- 26 {AI95-00318-02} A return statement (see 6.5) or a `requeue_statement` (see 9.5.4) may be used to complete the execution of an `accept_statement` or an `entry_body`. 29/2
- Ramification:** An `accept_statement` need not have a `handled_sequence_of_statements` even if the corresponding entry has parameters. Equally, it can have a `handled_sequence_of_statements` even if the corresponding entry has no parameters. 29.a
- Ramification:** A single entry overloads a subprogram, an enumeration literal, or another single entry if they have the same `defining_identifier`. Overloading is not allowed for entry family names. A single entry or an entry of an entry family can be renamed as a procedure as explained in 8.5.4. 29.b

- 30 27 The condition in the `entry_barrier` may reference anything visible except the formal parameters of the entry. This includes the entry index (if any), the components (including discriminants) of the protected object, the `Count` attribute of an entry of that protected object, and data global to the protected unit.
- 31 The restriction against referencing the formal parameters within an `entry_barrier` ensures that all calls of the same entry see the same barrier value. If it is necessary to look at the parameters of an entry call before deciding whether to handle it, the `entry_barrier` can be “**when True**” and the caller can be queued (on some private entry) when its parameters indicate that it cannot be handled immediately.

Examples

32 *Examples of entry declarations:*

```
33  entry Read(V : out Item);
34  entry Seize;
35  entry Request(Level) (D : Item); -- a family of entries
```

34 *Examples of accept statements:*

```
35  accept Shut_Down;
36  accept Read(V : out Item) do
37      V := Local_Item;
38  end Read;
39  accept Request(Low) (D : Item) do
40      ...
41  end Request;
```

Extensions to Ada 83

- 37.a The syntax rule for `entry_body` is new.
- 37.b `Accept_statements` can now have `exception_handlers`.

Wording Changes from Ada 95

- 37.c/2 {8652/0002} {AI95-00171-01} **Corrigendum:** Clarified the elaboration of per-object constraints.
- 37.d/2 {AI95-00397-01} `Overriding_indicators` can be used on entries; this is only useful when a task or protected type inherits from an interface.

Extensions to Ada 2005

- 37.e/3 {AI05-0183-1} An optional `aspect_specification` can be used in an `entry_declaration`. This is described in 13.1.1.

9.5.3 Entry Calls

- 1 [An `entry_call_statement` (an *entry call*) can appear in various contexts.] A *simple* entry call is a stand-alone statement that represents an unconditional call on an entry of a target task or a protected object. [Entry calls can also appear as part of `select_statements` (see 9.7).]

Syntax

2 `entry_call_statement ::= entry_name [actual_parameter_part];`

Name Resolution Rules

- 3 The *entry_name* given in an `entry_call_statement` shall resolve to denote an entry. The rules for parameter associations are the same as for subprogram calls (see 6.4 and 6.4.1).

Static Semantics

- 4 [The *entry_name* of an `entry_call_statement` specifies (explicitly or implicitly) the target object of the call, the entry or entry family, and the entry index, if any (see 9.5).]

Dynamic Semantics

Under certain circumstances (detailed below), an entry of a task or protected object is checked to see whether it is *open* or *closed*: 5

- {AI05-0264-1} An entry of a task is open if the task is blocked on an `accept_statement` that corresponds to the entry (see 9.5.2), or on a `selective_accept` (see 9.7.1) with an open `accept_alternative` that corresponds to the entry; otherwise, it is closed. 6/3
- {AI05-0264-1} An entry of a protected object is open if the condition of the `entry_barrier` of the corresponding `entry_body` evaluates to True; otherwise, it is closed. If the evaluation of the condition propagates an exception, the exception `Program_Error` is propagated to all current callers of all entries of the protected object. 7/3

Reason: An exception during barrier evaluation is considered essentially a fatal error. All current entry callers are notified with a `Program_Error`. In a fault-tolerant system, a protected object might provide a `Reset` protected procedure, or equivalent, to support attempts to restore such a "broken" protected object to a reasonable state. 7.a

Discussion: Note that the definition of when a task entry is open is based on the state of the (accepting) task, whereas the "openness" of a protected entry is defined only when it is explicitly checked, since the barrier expression needs to be evaluated. Implementation permissions are given (below) to allow implementations to evaluate the barrier expression more or less often than it is checked, but the basic semantic model presumes it is evaluated at the times when it is checked. 7.b

For the execution of an `entry_call_statement`, evaluation of the name and of the parameter associations is as for a subprogram call (see 6.4). The entry call is then *issued*: For a call on an entry of a protected object, a new protected action is started on the object (see 9.5.1). The named entry is checked to see if it is open; if open, the entry call is said to be *selected immediately*, and the execution of the call proceeds as follows: 8

- For a call on an open entry of a task, the accepting task becomes ready and continues the execution of the corresponding `accept_statement` (see 9.5.2). 9
- For a call on an open entry of a protected object, the corresponding `entry_body` is executed (see 9.5.2) as part of the protected action. 10

If the `accept_statement` or `entry_body` completes other than by a requeue (see 9.5.4), return is made to the caller (after servicing the entry queues — see below); any necessary assigning back of formal to actual parameters occurs, as for a subprogram call (see 6.4.1); such assignments take place outside of any protected action. 11

Ramification: The return to the caller will generally not occur until the protected action completes, unless some other thread of control is given the job of completing the protected action and releasing the associated execution resource. 11.a

If the named entry is closed, the entry call is added to an *entry queue* (as part of the protected action, for a call on a protected entry), and the call remains queued until it is selected or cancelled; there is a separate (logical) entry queue for each entry of a given task or protected object [(including each entry of an entry family)]. 12

When a queued call is *selected*, it is removed from its entry queue. Selecting a queued call from a particular entry queue is called *servicing* the entry queue. An entry with queued calls can be serviced under the following circumstances: 13

- When the associated task reaches a corresponding `accept_statement`, or a `selective_accept` with a corresponding open `accept_alternative`; 14
- If after performing, as part of a protected action on the associated protected object, an operation on the object other than a call on a protected function, the entry is checked and found to be open. 15

If there is at least one call on a queue corresponding to an open entry, then one such call is selected according to the *entry queuing policy* in effect (see below), and the corresponding `accept_statement` or `entry_body` is executed as above for an entry call that is selected immediately. 16

- 17 The entry queuing policy controls selection among queued calls both for task and protected entry queues. The default entry queuing policy is to select calls on a given entry queue in order of arrival. If calls from two or more queues are simultaneously eligible for selection, the default entry queuing policy does not specify which queue is serviced first. Other entry queuing policies can be specified by pragmas (see D.4).
- 18 For a protected object, the above servicing of entry queues continues until there are no open entries with queued calls, at which point the protected action completes.
- 18.a **Discussion:** While servicing the entry queues of a protected object, no new calls can be added to any entry queue of the object, except due to an internal requeue (see 9.5.4). This is because the first step of a call on a protected entry is to start a new protected action, which implies acquiring (for exclusive read-write access) the execution resource associated with the protected object, which cannot be done while another protected action is already in progress.
- 19 For an entry call that is added to a queue, and that is not the `triggering_statement` of an `asynchronous_select` (see 9.7.4), the calling task is blocked until the call is cancelled, or the call is selected and a corresponding `accept_statement` or `entry_body` completes without requeuing. In addition, the calling task is blocked during a rendezvous.
- 19.a **Ramification:** For a call on a protected entry, the caller is not blocked if the call is selected immediately, unless a requeue causes the call to be queued.
- 20 An attempt can be made to cancel an entry call upon an abort (see 9.8) and as part of certain forms of `select_statement` (see 9.7.2, 9.7.3, and 9.7.4). The cancellation does not take place until a point (if any) when the call is on some entry queue, and not protected from cancellation as part of a requeue (see 9.5.4); at such a point, the call is removed from the entry queue and the call completes due to the cancellation. The cancellation of a call on an entry of a protected object is a protected action[, and as such cannot take place while any other protected action is occurring on the protected object. Like any protected action, it includes servicing of the entry queues (in case some entry barrier depends on a Count attribute).]
- 20.a/2 **Implementation Note:** {AI95-00114-01} In the case of an attempted cancellation due to abort, this removal might have to be performed by the calling task itself if the ceiling priority of the protected object is lower than the priority of the task initiating the abort.
- 21 A call on an entry of a task that has already completed its execution raises the exception `Tasking_Error` at the point of the call; similarly, this exception is raised at the point of the call if the called task completes its execution or becomes abnormal before accepting the call or completing the rendezvous (see 9.8). This applies equally to a simple entry call and to an entry call as part of a `select_statement`.

Implementation Permissions

- 22 An implementation may perform the sequence of steps of a protected action using any thread of control; it need not be that of the task that started the protected action. If an `entry_body` completes without requeuing, then the corresponding calling task may be made ready without waiting for the entire protected action to complete.
- 22.a **Reason:** These permissions are intended to allow flexibility for implementations on multiprocessors. On a monoprocessor, which thread of control executes the protected action is essentially invisible, since the thread is not abortable in any case, and the "current_task" function is not guaranteed to work during a protected action (see C.7.1).
- 23 When the entry of a protected object is checked to see whether it is open, the implementation need not reevaluate the condition of the corresponding `entry_barrier` if no variable or attribute referenced by the condition (directly or indirectly) has been altered by the execution (or cancellation) of a protected procedure or entry call on the object since the condition was last evaluated.
- 23.a **Ramification:** Changes to variables referenced by an entry barrier that result from actions outside of a protected procedure or entry call on the protected object need not be "noticed." For example, if a global variable is referenced by an entry barrier, it should not be altered (except as part of a protected action on the object) any time after the barrier is first evaluated. In other words, globals can be used to "parameterize" a protected object, but they cannot reliably be used to control it after the first use of the protected object.

- Implementation Note:** Note that even if a global variable is volatile, the implementation need only reevaluate a barrier if the global is updated during a protected action on the protected object. This ensures that an entry-open bit-vector implementation approach is possible, where the bit-vector is computed at the end of a protected action, rather than upon each entry call. 23.b
- An implementation may evaluate the conditions of all `entry_barriers` of a given protected object any time any entry of the object is checked to see if it is open. 24
- Ramification:** In other words, any side effects of evaluating an entry barrier should be innocuous, since an entry barrier might be evaluated more or less often than is implied by the "official" dynamic semantics. 24.a
- Implementation Note:** It is anticipated that when the number of entries is known to be small, all barriers will be evaluated any time one of them needs to be, to produce an "entry-open bit-vector." The appropriate bit will be tested when the entry is called, and only if the bit is false will a check be made to see whether the bit-vector might need to be recomputed. This should allow an implementation to maximize the performance of a call on an open entry, which seems like the most important case. 24.b
- In addition to the entry-open bit-vector, an "is-valid" bit is needed per object, which indicates whether the current bit-vector setting is valid. A "depends-on-Count-attribute" bit is needed per type. The "is-valid" bit is set to false (as are all the bits of the bit-vector) when the protected object is first created, as well as any time an exception is propagated from computing the bit-vector. Is-valid would also be set false any time the Count is changed and "depends-on-Count-attribute" is true for the type, or a protected procedure or entry returns indicating it might have updated a variable referenced in some barrier. 24.c
- A single procedure can be compiled to evaluate all of the barriers, set the entry-open bit-vector accordingly, and set the is-valid bit to true. It could have a "when others" handler to set them all false, and call a routine to propagate `Program_Error` to all queued callers. 24.d
- For protected types where the number of entries is not known to be small, it makes more sense to evaluate a barrier only when the corresponding entry is checked to see if it is open. It isn't worth saving the state of the entry between checks, because of the space that would be required. Furthermore, the entry queues probably want to take up space only when there is actually a caller on them, so rather than an array of all entry queues, a linked list of nonempty entry queues make the most sense in this case, with the first caller on each entry queue acting as the queue header. 24.e
- When an attempt is made to cancel an entry call, the implementation need not make the attempt using the thread of control of the task (or interrupt) that initiated the cancellation; in particular, it may use the thread of control of the caller itself to attempt the cancellation, even if this might allow the entry call to be selected in the interim. 25
- Reason:** Because cancellation of a protected entry call is a protected action (which helps make the Count attribute of a protected entry meaningful), it might not be practical to attempt the cancellation from the thread of control that initiated the cancellation. For example, if the cancellation is due to the expiration of a delay, it is unlikely that the handler of the timer interrupt could perform the necessary protected action itself (due to being on the interrupt level). Similarly, if the cancellation is due to an abort, it is possible that the task initiating the abort has a priority higher than the ceiling priority of the protected object (for implementations that support ceiling priorities). Similar considerations could apply in a multiprocessor situation. 25.a
- NOTES
- 28 If an exception is raised during the execution of an `entry_body`, it is propagated to the corresponding caller (see 11.4). 26
- 29 For a call on a protected entry, the entry is checked to see if it is open prior to queuing the call, and again thereafter if its Count attribute (see 9.9) is referenced in some entry barrier. 27
- Ramification:** Given this, extra care is required if a reference to the Count attribute of an entry appears in the entry's own barrier. 27.a
- Reason:** An entry is checked to see if it is open prior to queuing to maximize the performance of a call on an open entry. 27.b
- 30 In addition to simple entry calls, the language permits timed, conditional, and asynchronous entry calls (see 9.7.2, 9.7.3, and see 9.7.4). 28
- Ramification:** A task can call its own entries, but the task will deadlock if the call is a simple entry call. 28.a
- 31 The condition of an `entry_barrier` is allowed to be evaluated by an implementation more often than strictly necessary, even if the evaluation might have side effects. On the other hand, an implementation need not reevaluate the condition if nothing it references was updated by an intervening protected action on the protected object, even if the condition references some global variable that might have been updated by an action performed from outside of a protected action. 29

Examples

30 *Examples of entry calls:*

```

31 Agent.Shut_Down;                -- see 9.1
   Parser.Next_Lexeme (E);        -- see 9.1
   Pool (5).Read (Next_Char);    -- see 9.1
   Controller.Request (Low) (Some_Item); -- see 9.1
   Flags (3).Seize;              -- see 9.4

```

9.5.4 Requeue Statements

1 [A `requeue_statement` can be used to complete an `accept_statement` or `entry_body`, while redirecting the corresponding entry call to a new (or the same) entry queue. Such a *requeue* can be performed with or without allowing an intermediate cancellation of the call, due to an abort or the expiration of a delay.]

Syntax

2/3 {AI05-0030-2} `requeue_statement ::= requeue procedure_or_entry_name [with abort];`

Name Resolution Rules

3/3 {AI05-0030-2} {AI05-0215-1} The *procedure_or_entry_name* of a `requeue_statement` shall resolve to denote a procedure or an entry (the *requeue target*). The profile of the entry, or the profile or prefixed profile of the procedure, shall either have no parameters, or be type conformant (see 6.3.1) with the profile of the innermost enclosing `entry_body` or `accept_statement`.

Legality Rules

4 A `requeue_statement` shall be within a callable construct that is either an `entry_body` or an `accept_statement`, and this construct shall be the innermost enclosing body or callable construct.

5/3 {AI05-0030-2} {AI05-0215-1} If the requeue target has parameters, then its (prefixed) profile shall be subtype conformant with the profile of the innermost enclosing callable construct.

5.1/3 {AI05-0030-2} {AI05-0215-1} If the target is a procedure, the name shall denote a renaming of an entry, or shall denote a view or a prefixed view of a primitive subprogram of a synchronized interface, where the first parameter of the unprefix view of the primitive subprogram shall be a controlling parameter, and the Synchronization aspect shall be specified with `synchronization_kind` `By_Entry` for the primitive subprogram.

6/3 {AI05-0030-2} In a `requeue_statement` of an `accept_statement` of some task unit, either the target object shall be a part of a formal parameter of the `accept_statement`, or the accessibility level of the target object shall not be equal to or statically deeper than any enclosing `accept_statement` of the task unit. In a `requeue_statement` of an `entry_body` of some protected unit, either the target object shall be a part of a formal parameter of the `entry_body`, or the accessibility level of the target object shall not be statically deeper than that of the `entry_declaration` for the `entry_body`.

6.a **Ramification:** In the `entry_body` case, the intent is that the target object can be global, or can be a component of the protected unit, but cannot be a local variable of the `entry_body`.

6.b **Reason:** These restrictions ensure that the target object of the requeue outlives the completion and finalization of the enclosing callable construct. They also prevent requeueing from a nested `accept_statement` on a parameter of an outer `accept_statement`, which could create some strange "long-distance" connections between an entry caller and its server.

6.c Note that in the strange case where a `task_body` is nested inside an `accept_statement`, it is permissible to requeue from an `accept_statement` of the inner `task_body` on parameters of the outer `accept_statement`. This is not a problem because all calls on the inner task have to complete before returning from the outer `accept_statement`, meaning no "dangling calls" will be created.

Implementation Note: By disallowing certain requeues, we ensure that the normal <code>terminate_alternative</code> rules remain sensible, and that explicit clearing of the entry queues of a protected object during finalization is rarely necessary. In particular, such clearing of the entry queues is necessary only (ignoring premature <code>Unchecked_Deallocation</code>) for protected objects declared in a <code>task_body</code> (or created by an allocator for an access type declared in such a body) containing one or more <code>requeue_statements</code> . Protected objects declared in subprograms, or at the library level, will never need to have their entry queues explicitly cleared during finalization.	6.d
<i>Dynamic Semantics</i>	
{AI05-0030-2} The execution of a <code>requeue_statement</code> proceeds by first evaluating the <code>procedure_or_entry_name</code> [], including the <code>prefix</code> identifying the target task or protected object and the <code>expression</code> identifying the entry within an entry family, if any]. The <code>entry_body</code> or <code>accept_statement</code> enclosing the <code>requeue_statement</code> is then completed[], finalized, and left (see 7.6.1)].	7/3
For the execution of a requeue on an entry of a target task, after leaving the enclosing callable construct, the named entry is checked to see if it is open and the requeued call is either selected immediately or queued, as for a normal entry call (see 9.5.3).	8
For the execution of a requeue on an entry of a target protected object, after leaving the enclosing callable construct:	9
<ul style="list-style-type: none"> • if the requeue is an internal requeue (that is, the requeue is back on an entry of the same protected object — see 9.5), the call is added to the queue of the named entry and the ongoing protected action continues (see 9.5.1); 	10
<p style="margin-left: 2em;">Ramification: Note that for an internal requeue, the call is queued without checking whether the target entry is open. This is because the entry queues will be serviced before the current protected action completes anyway, and considering the requeued call immediately might allow it to "jump" ahead of existing callers on the same queue.</p>	10.a
<ul style="list-style-type: none"> • if the requeue is an external requeue (that is, the target protected object is not implicitly the same as the current object — see 9.5), a protected action is started on the target object and proceeds as for a normal entry call (see 9.5.3). 	11
{AI05-0030-2} If the requeue target named in the <code>requeue_statement</code> has formal parameters, then during the execution of the <code>accept_statement</code> or <code>entry_body</code> corresponding to the new entry, the formal parameters denote the same objects as did the corresponding formal parameters of the callable construct completed by the requeue. [In any case, no parameters are specified in a <code>requeue_statement</code> ; any parameter passing is implicit.]	12/3
If the <code>requeue_statement</code> includes the reserved words with abort (it is a <i>requeue-with-abort</i>), then:	13
<ul style="list-style-type: none"> • if the original entry call has been aborted (see 9.8), then the requeue acts as an abort completion point for the call, and the call is cancelled and no requeue is performed; 	14
<ul style="list-style-type: none"> • if the original entry call was timed (or conditional), then the original expiration time is the expiration time for the requeued call. 	15
If the reserved words with abort do not appear, then the call remains protected against cancellation while queued as the result of the <code>requeue_statement</code> .	16
<p style="margin-left: 2em;">Ramification: This protection against cancellation lasts only until the call completes or a subsequent <code>requeue-with-abort</code> is performed on the call.</p>	16.a
<p style="margin-left: 2em;">Reason: We chose to protect a requeue, by default, against abort or cancellation. This seemed safer, since it is likely that extra steps need to be taken to allow for possible cancellation once the servicing of an entry call has begun. This also means that in the absence of with abort the usual Ada 83 behavior is preserved, namely that once an entry call is accepted, it cannot be cancelled until it completes.</p>	16.b
NOTES	
32 A requeue is permitted from a single entry to an entry of an entry family, or vice-versa. The entry index, if any, plays no part in the subtype conformance check between the profiles of the two entries; an entry index is part of the <code>entry_name</code> for an entry of a family.	17

Examples

18 *Examples of requeue statements:*

```
19   requeue Request (Medium) with abort;
      -- requeue on a member of an entry family of the current task, see 9.1
20   requeue Flags (I) .Seize;
      -- requeue on an entry of an array component, see 9.4
```

Extensions to Ada 83

20.a The requeue_statement is new.

Extensions to Ada 2005

20.b/3 {AI05-0030-2} {AI05-0215-1} Added the ability to requeue on operations of synchronized interfaces that are declared to be an entry.

9.6 Delay Statements, Duration, and Time

1 [A delay_statement is used to block further execution until a specified *expiration time* is reached. The expiration time can be specified either as a particular point in time (in a delay_until_statement), or in seconds from the current time (in a delay_relative_statement). The language-defined package Calendar provides definitions for a type Time and associated operations, including a function Clock that returns the current time.]

Syntax

```
2   delay_statement ::= delay_until_statement | delay_relative_statement
3   delay_until_statement ::= delay until delay_expression;
4   delay_relative_statement ::= delay delay_expression;
```

Name Resolution Rules

5 The expected type for the *delay_expression* in a delay_relative_statement is the predefined type Duration. The *delay_expression* in a delay_until_statement is expected to be of any nonlimited type.

Legality Rules

6/3 {AI05-0092-1} There can be multiple time bases, each with a corresponding clock, and a corresponding *time type*. The type of the *delay_expression* in a delay_until_statement shall be a time type — either the type Time defined in the language-defined package Calendar (see below), the type Time in the package Real_Time (see D.8), or some other implementation-defined time type.

6.a **Implementation defined:** Any implementation-defined time types.

Static Semantics

7 [There is a predefined fixed point type named Duration, declared in the visible part of package Standard;] a value of type Duration is used to represent the length of an interval of time, expressed in seconds. [The type Duration is not specific to a particular time base, but can be used with any time base.]

8/3 {AI05-0092-1} A value of the type Time in package Calendar, or of some other time type, represents a time as reported by a corresponding clock.

9 The following language-defined library package exists:

```
10   package Ada.Calendar is
      type Time is private;
```

```

{AI95-00351-01}    subtype Year_Number is Integer range 1901 .. 2399;           11/2
    subtype Month_Number is Integer range 1 .. 12;
    subtype Day_Number is Integer range 1 .. 31;
    subtype Day_Duration is Duration range 0.0 .. 86_400.0;

    Reason: {AI95-00351-01} A range of 500 years was chosen, as that only requires one extra bit for the year as compared to Ada 95. This was done to minimize disruptions with existing implementations. (One implementor reports that their time values represent nanoseconds, and this year range requires 63.77 bits to represent.) 11.a/2

function Clock return Time;                                               12
function Year (Date : Time) return Year_Number;                            13
function Month (Date : Time) return Month_Number;
function Day (Date : Time) return Day_Number;
function Seconds (Date : Time) return Day_Duration;

procedure Split (Date : in Time;                                         14
                Year : out Year_Number;
                Month : out Month_Number;
                Day : out Day_Number;
                Seconds : out Day_Duration);

function Time_Of (Year : Year_Number;                                     15

Dynamic Semantics

For the execution of a `delay_statement`, the `delay_expression` is first evaluated. For a `delay_until_statement`, the expiration time for the delay is the value of the `delay_expression`, in the time base associated with the type of the expression. For a `delay_relative_statement`, the expiration time is defined as the current time, in the time base associated with relative delays, plus the value of the `delay_expression` converted to the type `Duration`, and then rounded up to the next clock tick. The time base associated with relative delays is as defined in D.9, “Delay Accuracy” or is implementation defined. 20

Implementation defined: The time base associated with relative delays. 20.a

Ramification: Rounding up to the next clock tick means that the reading of the delay-relative clock when the delay expires should be no less than the current reading of the delay-relative clock plus the specified duration. 20.b

The task executing a `delay_statement` is blocked until the expiration time is reached, at which point it becomes ready again. If the expiration time has already passed, the task is not blocked. 21

Discussion: For a `delay_relative_statement`, this case corresponds to when the value of the `delay_expression` is zero or negative. 21.a

Even though the task is not blocked, it might be put back on the end of its ready queue. See D.2, “Priority Scheduling”. 21.b

{AI05-0092-1} If an attempt is made to *cancel* the `delay_statement` [(as part of an `asynchronous_select` or `abort` — see 9.7.4 and 9.8)], the statement is cancelled if the expiration time has not yet passed, thereby completing the `delay_statement`. 22/3

- 22.a **Reason:** This is worded this way so that in an `asynchronous_select` where the `triggering_statement` is a `delay_statement`, an attempt to cancel the delay when the `abortable_part` completes is ignored if the expiration time has already passed, in which case the optional statements of the `triggering_alternative` are executed.
- 23 The time base associated with the type `Time` of package `Calendar` is implementation defined. The function `Clock` of package `Calendar` returns a value representing the current time for this time base. [The implementation-defined value of the named number `System.Tick` (see 13.7) is an approximation of the length of the real-time interval during which the value of `Calendar.Clock` remains constant.]
- 23.a **Implementation defined:** The time base of the type `Calendar.Time`.
- 24/2 `{AI95-00351-01}` The functions `Year`, `Month`, `Day`, and `Seconds` return the corresponding values for a given value of the type `Time`, as appropriate to an implementation-defined time zone; the procedure `Split` returns all four corresponding values. Conversely, the function `Time_Of` combines a year number, a month number, a day number, and a duration, into a value of type `Time`. The operators `"+"` and `"-"` for addition and subtraction of times and durations, and the relational operators for times, have the conventional meaning.
- 24.a/2 **Implementation defined:** The time zone used for package `Calendar` operations.
- 24.b/3 **Ramification:** `{AI05-0119-1}` The behavior of these values and subprograms if the time zone changes is also implementation-defined. In particular, the changes associated with summer time adjustments (like Daylight Savings Time in the United States) should be treated as a change in the implementation-defined time zone. The language does not specify whether the time zone information is stored in values of type `Time`; therefore the results of binary operators are unspecified when the operands are the two values with different effective time zones. In particular, the results of `"-"` may differ from the "real" result by the difference in the time zone adjustment. Similarly, the result of `UTC_Time_Offset` (see 9.6.1) may or may not reflect a time zone adjustment.
- 25 If `Time_Of` is called with a seconds value of `86_400.0`, the value returned is equal to the value of `Time_Of` for the next day with a seconds value of `0.0`. The value returned by the function `Seconds` or through the `Seconds` parameter of the procedure `Split` is always less than `86_400.0`.
- 26/1 `{8652/0030}` `{AI95-00113-01}` The exception `Time_Error` is raised by the function `Time_Of` if the actual parameters do not form a proper date. This exception is also raised by the operators `"+"` and `"-"` if the result is not representable in the type `Time` or `Duration`, as appropriate. This exception is also raised by the functions `Year`, `Month`, `Day`, and `Seconds` and the procedure `Split` if the year number of the given date is outside of the range of the subtype `Year_Number`.
- 26.a/1 **To be honest:** `{8652/0106}` `{AI95-00160-01}` By "proper date" above we mean that the given year has a month with the given day. For example, February 29th is a proper date only for a leap year. We do not mean to include the `Seconds` in this notion; in particular, we do not mean to require implementations to check for the "missing hour" that occurs when Daylight Savings Time starts in the spring.
- 26.b/2 **Reason:** `{8652/0030}` `{AI95-00113-01}` `{AI95-00351-01}` We allow `Year` and `Split` to raise `Time_Error` because the arithmetic operators are allowed (but not required) to produce times that are outside the range of years from 1901 to 2399. This is similar to the way integer operators may return values outside the base range of their type so long as the value is mathematically correct. We allow the functions `Month`, `Day` and `Seconds` to raise `Time_Error` so that they can be implemented in terms of `Split`.

Implementation Requirements

- 27 The implementation of the type `Duration` shall allow representation of time intervals (both positive and negative) up to at least 86400 seconds (one day); `Duration'Small` shall not be greater than twenty milliseconds. The implementation of the type `Time` shall allow representation of all dates with year numbers in the range of `Year_Number`]; it may allow representation of other dates as well (both earlier and later).]

Implementation Permissions

- 28/3 `{AI05-0092-1}` An implementation may define additional time types.

An implementation may raise `Time_Error` if the value of a *delay_expression* in a `delay_until_statement` of a `select_statement` represents a time more than 90 days past the current time. The actual limit, if any, is implementation-defined. 29

Implementation defined: Any limit on `delay_until_statements` of `select_statements`. 29.a

Implementation Note: This allows an implementation to implement `select_statement` timeouts using a representation that does not support the full range of a time type. In particular 90 days of seconds can be represented in 23 bits, allowing a signed 24-bit representation for the seconds part of a timeout. There is no similar restriction allowed for stand-alone `delay_until_statements`, as these can be implemented internally using a loop if necessary to accommodate a long delay. 29.b

Implementation Advice

Whenever possible in an implementation, the value of `Duration'Small` should be no greater than 100 microseconds. 30

Implementation Note: This can be satisfied using a 32-bit 2's complement representation with a *small* of $2.0^{*(-14)}$ — that is, 61 microseconds — and a range of $\pm 2.0^{*17}$ — that is, 131_072.0. 30.a

Implementation Advice: The value of `Duration'Small` should be no greater than 100 microseconds. 30.b/2

The time base for `delay_relative_statements` should be monotonic; it need not be the same time base as used for `Calendar.Clock`. 31

Implementation Advice: The time base for `delay_relative_statements` should be monotonic. 31.a/2

NOTES

33 A `delay_relative_statement` with a negative value of the *delay_expression* is equivalent to one with a zero value. 32

34 A `delay_statement` may be executed by the environment task; consequently `delay_statements` may be executed as part of the elaboration of a `library_item` or the execution of the main subprogram. Such statements delay the environment task (see 10.2). 33

35 A `delay_statement` is an abort completion point and a potentially blocking operation, even if the task is not actually blocked. 34

36 There is no necessary relationship between `System.Tick` (the resolution of the clock of package `Calendar`) and `Duration'Small` (the *small* of type `Duration`). 35

Ramification: The inaccuracy of the `delay_statement` has no relation to `System.Tick`. In particular, it is possible that the clock used for the `delay_statement` is less accurate than `Calendar.Clock`. 35.a

We considered making `Tick` a run-time-determined quantity, to allow for easier configurability. However, this would not be upward compatible, and the desired configurability can be achieved using functionality defined in Annex D, “Real-Time Systems”. 35.b

37 Additional requirements associated with `delay_statements` are given in D.9, “Delay Accuracy”. 36

Examples

Example of a relative delay statement: 37

```
delay 3.0;  -- delay 3.0 seconds 38
```

Example of a periodic task: 39

```
declare
  use Ada.Calendar;
  Next_Time : Time := Clock + Period;
  -- Period is a global constant of type Duration
begin
  loop  -- repeated every Period seconds
    delay until Next_Time;
    ... -- perform some actions
    Next_Time := Next_Time + Period;
  end loop;
end;
```

40

Inconsistencies With Ada 83

- 40.a For programs that raise `Time_Error` on "+" or "-" in Ada 83, the exception might be deferred until a call on `Split` or `Year_Number`, or might not be raised at all (if the offending time is never `Split` after being calculated). This should not affect typical programs, since they deal only with times corresponding to the relatively recent past or near future.

Extensions to Ada 83

- 40.b The syntax rule for `delay_statement` is modified to allow `delay_until_statements`.
- 40.c/2 *{AI95-00351-01}* The type `Time` may represent dates with year numbers outside of `Year_Number`. Therefore, the operations "+" and "-" need only raise `Time_Error` if the result is not representable in `Time` (or `Duration`); also, `Split` or `Year` will now raise `Time_Error` if the year number is outside of `Year_Number`. This change is intended to simplify the implementation of "+" and "-" (allowing them to depend on overflow for detecting when to raise `Time_Error`) and to allow local time zone information to be considered at the time of `Split` rather than `Clock` (depending on the implementation approach). For example, in a POSIX environment, it is natural for the type `Time` to be based on GMT, and the results of procedure `Split` (and the functions `Year`, `Month`, `Day`, and `Seconds`) to depend on local time zone information. In other environments, it is more natural for the type `Time` to be based on the local time zone, with the results of `Year`, `Month`, `Day`, and `Seconds` being pure functions of their input.
- 40.d/2 *This paragraph was deleted. {AI95-00351-01}*

Inconsistencies With Ada 95

- 40.e/2 *{AI95-00351-01}* The upper bound of `Year_Number` has been changed to avoid a year 2100 problem. A program which expects years past 2099 to raise `Constraint_Error` will fail in Ada 2005. We don't expect there to be many programs which are depending on an exception to be raised. A program that uses `Year_Number'Last` as a magic number may also fail if values of `Time` are stored outside of the program. Note that the lower bound of `Year_Number` wasn't changed, because it is not unusual to use that value in a constant to represent an unknown time.

Wording Changes from Ada 95

- 40.f/2 *{8652/0002} {AI95-00171-01}* **Corrigendum:** Clarified that `Month`, `Day`, and `Seconds` can raise `Time_Error`.

9.6.1 Formatting, Time Zones, and other operations for Time

Static Semantics

- 1/2 *{AI95-00351-01} {AI95-00427-01}* The following language-defined library packages exist:
- 2/2 **package** `Ada.Calendar.Time_Zones` **is**
- 3/2 *-- Time zone manipulation:*
- 4/2 **type** `Time_Offset` **is range** `-28*60 .. 28*60;`
- 4.a/2 **Reason:** We want to be able to specify the difference between any two arbitrary time zones. You might think that 1440 (24 hours) would be enough, but there are places (like Tonga, which is UTC+13hr) which are more than 12 hours than UTC. Combined with summer time (known as daylight saving time in some parts of the world) – which switches opposite in the northern and southern hemispheres – and even greater differences are possible. We know of cases of a 26 hours difference, so we err on the safe side by selecting 28 hours as the limit.
- 5/2 `Unknown_Zone_Error` : **exception;**
- 6/2 **function** `UTC_Time_Offset` (`Date` : `Time` := `Clock`) **return** `Time_Offset;`
- 7/2 **end** `Ada.Calendar.Time_Zones;`
- 8/2 **package** `Ada.Calendar.Arithmetic` **is**
- 9/2 *-- Arithmetic on days:*
- 10/2 **type** `Day_Count` **is range**
`-366*(1+Year_Number'Last - Year_Number'First)`
`..`
`366*(1+Year_Number'Last - Year_Number'First);`
- 11/2 **subtype** `Leap_Seconds_Count` **is** `Integer` **range** `-2047 .. 2047;`
- 11.a/2 **Reason:** The maximum number of leap seconds is likely to be much less than this, but we don't want to reach the limit too soon if the earth's behavior suddenly changes. We believe that the maximum number is 1612, based on the current rules, but that number is too weird to use here.

40/2     {AI95-00351-01} Type Time_Offset represents the number of minutes difference between the
implementation-defined time zone used by Calendar and another time zone.

41/2     function UTC_Time_Offset (Date : Time := Clock) return Time_Offset;

42/3     {AI95-00351-01} {AI05-0119-1} {AI05-0269-1} Returns, as a number of minutes, the result of
subtracting the implementation-defined time zone of Calendar from UTC time, at the time Date.

```

If the time zone of the Calendar implementation is unknown, then <code>Unknown_Zone_Error</code> is raised.		
Ramification: <i>{AI05-0119-1}</i>	In North America, the result will be negative; in Europe, the result will be zero or positive.	42.a.1/3
Discussion:	The <code>Date</code> parameter is needed to take into account time differences caused by daylight-savings time and other time changes. This parameter is measured in the time zone of <code>Calendar</code> , if any, not necessarily the UTC time zone.	42.a/2
	Other time zones can be supported with a child package. We don't define one because of the lack of agreement on the definition of a time zone.	42.b/2
	The accuracy of this routine is not specified; the intent is that the facilities of the underlying target operating system are used to implement it.	42.c/2
procedure	<code>Difference (Left, Right : in Time; Days : out Day_Count; Seconds : out Duration; Leap_Seconds : out Leap_Seconds_Count);</code>	43/2
<i>{AI95-00351-01}</i> <i>{AI95-00427-01}</i>	Returns the difference between <code>Left</code> and <code>Right</code> . <code>Days</code> is the number of days of difference, <code>Seconds</code> is the remainder seconds of difference excluding leap seconds, and <code>Leap_Seconds</code> is the number of leap seconds. If <code>Left < Right</code> , then <code>Seconds <= 0.0</code> , <code>Days <= 0</code> , and <code>Leap_Seconds <= 0</code> . Otherwise, all values are nonnegative. The absolute value of <code>Seconds</code> is always less than <code>86_400.0</code> . For the returned values, if <code>Days = 0</code> , then <code>Seconds + Duration(Leap_Seconds) = Calendar."-" (Left, Right)</code> .	44/2
Discussion:	<code>Leap_Seconds</code> , if any, are not included in <code>Seconds</code> . However, <code>Leap_Seconds</code> should be included in calculations using the operators defined in <code>Calendar</code> , as is specified for <code>"-"</code> above.	44.a/2
function	<code>"+" (Left : Time; Right : Day_Count) return Time;</code>	45/2
function	<code>"+" (Left : Day_Count; Right : Time) return Time;</code>	
<i>{AI95-00351-01}</i>	Adds a number of days to a time value. <code>Time_Error</code> is raised if the result is not representable as a value of type <code>Time</code> .	46/2
function	<code>"-" (Left : Time; Right : Day_Count) return Time;</code>	47/2
<i>{AI95-00351-01}</i>	Subtracts a number of days from a time value. <code>Time_Error</code> is raised if the result is not representable as a value of type <code>Time</code> .	48/2
function	<code>"-" (Left, Right : Time) return Day_Count;</code>	49/2
<i>{AI95-00351-01}</i>	Subtracts two time values, and returns the number of days between them. This is the same value that <code>Difference</code> would return in <code>Days</code> .	50/2
function	<code>Day_of_Week (Date : Time) return Day_Name;</code>	51/2
<i>{AI95-00351-01}</i>	Returns the day of the week for <code>Time</code> . This is based on the <code>Year</code> , <code>Month</code> , and <code>Day</code> values of <code>Time</code> .	52/2
function	<code>Year (Date : Time; Time_Zone : Time_Zones.Time_Offset := 0) return Year_Number;</code>	53/2
<i>{AI95-00427-01}</i>	Returns the year for <code>Date</code> , as appropriate for the specified time zone offset.	54/2
function	<code>Month (Date : Time; Time_Zone : Time_Zones.Time_Offset := 0) return Month_Number;</code>	55/2
<i>{AI95-00427-01}</i>	Returns the month for <code>Date</code> , as appropriate for the specified time zone offset.	56/2

- 57/2 **function** Day (Date : Time;
 Time_Zone : Time_Zones.Time_Offset := 0)
 return Day_Number;
- 58/2 {AI95-00427-01} Returns the day number for Date, as appropriate for the specified time zone offset.
- 59/2 **function** Hour (Date : Time;
 Time_Zone : Time_Zones.Time_Offset := 0)
 return Hour_Number;
- 60/2 {AI95-00351-01} Returns the hour for Date, as appropriate for the specified time zone offset.
- 61/2 **function** Minute (Date : Time;
 Time_Zone : Time_Zones.Time_Offset := 0)
 return Minute_Number;
- 62/2 {AI95-00351-01} Returns the minute within the hour for Date, as appropriate for the specified time zone offset.
- 63/2 **function** Second (Date : Time)
 return Second_Number;
- 64/2 {AI95-00351-01} {AI95-00427-01} Returns the second within the hour and minute for Date.
- 65/2 **function** Sub_Second (Date : Time)
 return Second_Duration;
- 66/2 {AI95-00351-01} {AI95-00427-01} Returns the fraction of second for Date (this has the same accuracy as Day_Duration). The value returned is always less than 1.0.
- 67/2 **function** Seconds_Of (Hour : Hour_Number;
 Minute : Minute_Number;
 Second : Second_Number := 0;
 Sub_Second : Second_Duration := 0.0)
 return Day_Duration;
- 68/2 {AI95-00351-01} {AI95-00427-01} Returns a Day_Duration value for the combination of the given Hour, Minute, Second, and Sub_Second. This value can be used in Calendar.Time_Of as well as the argument to Calendar."+" and Calendar."-". If Seconds_Of is called with a Sub_Second value of 1.0, the value returned is equal to the value of Seconds_Of for the next second with a Sub_Second value of 0.0.
- 69/2 **procedure** Split (Seconds : **in** Day_Duration;
 Hour : **out** Hour_Number;
 Minute : **out** Minute_Number;
 Second : **out** Second_Number;
 Sub_Second : **out** Second_Duration);
- 70/3 {AI95-00351-01} {AI95-00427-01} {AI05-0238-1} Splits Seconds into Hour, Minute, Second and Sub_Second in such a way that the resulting values all belong to their respective subtypes. The value returned in the Sub_Second parameter is always less than 1.0. If Seconds = 86400.0, Split propagates Time_Error.
- 70.a/2 **Ramification:** There is only one way to do the split which meets all of the requirements.
- 70.b/3 **Reason:** {AI05-0238-1} If Seconds = 86400.0, one of the returned values would have to be out of its defined range (either Sub_Second = 1.0 or Hour = 24 with the other value being 0). This doesn't seem worth breaking the invariants.

```

function Time_Of (Year      : Year_Number;
                  Month     : Month_Number;
                  Day       : Day_Number;
                  Hour      : Hour_Number;
                  Minute    : Minute_Number;
                  Second     : Second_Number;
                  Sub_Second : Second_Duration := 0.0;
                  Leap_Second : Boolean := False;
                  Time_Zone  : Time_Zones.Time_Offset := 0)
    return Time;

```

71/2

{AI95-00351-01} *{AI95-00427-01}* If Leap_Second is False, returns a Time built from the date and time values, relative to the specified time zone offset. If Leap_Second is True, returns the Time that represents the time within the leap second that is one second later than the time specified by the other parameters. Time_Error is raised if the parameters do not form a proper date or time. If Time_Of is called with a Sub_Second value of 1.0, the value returned is equal to the value of Time_Of for the next second with a Sub_Second value of 0.0.

72/2

Discussion: Time_Error should be raised if Leap_Second is True, and the date and time values do not represent the second before a leap second. A leap second always occurs at midnight UTC, and is 23:59:60 UTC in ISO notation. So, if the time zone is UTC and Leap_Second is True, if any of Hour /= 23, Minute /= 59, or Second /= 59, then Time_Error should be raised. However, we do not say that, because other time zones will have different values where a leap second is allowed.

72.a/2

```

function Time_Of (Year      : Year_Number;
                  Month     : Month_Number;
                  Day       : Day_Number;
                  Seconds    : Day_Duration := 0.0;
                  Leap_Second : Boolean := False;
                  Time_Zone  : Time_Zones.Time_Offset := 0)
    return Time;

```

73/2

{AI95-00351-01} *{AI95-00427-01}* If Leap_Second is False, returns a Time built from the date and time values, relative to the specified time zone offset. If Leap_Second is True, returns the Time that represents the time within the leap second that is one second later than the time specified by the other parameters. Time_Error is raised if the parameters do not form a proper date or time. If Time_Of is called with a Seconds value of 86_400.0, the value returned is equal to the value of Time_Of for the next day with a Seconds value of 0.0.

74/2

```

procedure Split (Date      : in Time;
                 Year      : out Year_Number;
                 Month     : out Month_Number;
                 Day       : out Day_Number;
                 Hour      : out Hour_Number;
                 Minute    : out Minute_Number;
                 Second     : out Second_Number;
                 Sub_Second : out Second_Duration;
                 Leap_Second : out Boolean;
                 Time_Zone  : in Time_Zones.Time_Offset := 0);

```

75/2

{AI95-00351-01} *{AI95-00427-01}* If Date does not represent a time within a leap second, splits Date into its constituent parts (Year, Month, Day, Hour, Minute, Second, Sub_Second), relative to the specified time zone offset, and sets Leap_Second to False. If Date represents a time within a leap second, set the constituent parts to values corresponding to a time one second earlier than that given by Date, relative to the specified time zone offset, and sets Leap_Seconds to True. The value returned in the Sub_Second parameter is always less than 1.0.

76/2

- 77/2 **procedure** Split (Date : **in** Time;
 Year : **out** Year_Number;
 Month : **out** Month_Number;
 Day : **out** Day_Number;
 Hour : **out** Hour_Number;
 Minute : **out** Minute_Number;
 Second : **out** Second_Number;
 Sub_Second : **out** Second_Duration;
 Time_Zone : **in** Time_Zones.Time_Offset := 0);
- 78/2 {AI95-00351-01} {AI95-00427-01} Splits Date into its constituent parts (Year, Month, Day, Hour, Minute, Second, Sub_Second), relative to the specified time zone offset. The value returned in the Sub_Second parameter is always less than 1.0.
- 79/2 **procedure** Split (Date : **in** Time;
 Year : **out** Year_Number;
 Month : **out** Month_Number;
 Day : **out** Day_Number;
 Seconds : **out** Day_Duration;
 Leap_Second: **out** Boolean;
 Time_Zone : **in** Time_Zones.Time_Offset := 0);
- 80/2 {AI95-00351-01} {AI95-00427-01} If Date does not represent a time within a leap second, splits Date into its constituent parts (Year, Month, Day, Seconds), relative to the specified time zone offset, and sets Leap_Second to False. If Date represents a time within a leap second, set the constituent parts to values corresponding to a time one second earlier than that given by Date, relative to the specified time zone offset, and sets Leap_Seconds to True. The value returned in the Seconds parameter is always less than 86_400.0.
- 81/2 **function** Image (Date : Time;
 Include_Time_Fraction : Boolean := False;
 Time_Zone : Time_Zones.Time_Offset := 0) **return** String;
- 82/2 {AI95-00351-01} Returns a string form of the Date relative to the given Time_Zone. The format is "Year-Month-Day Hour:Minute:Second", where the Year is a 4-digit value, and all others are 2-digit values, of the functions defined in Calendar and Calendar.Formatting, including a leading zero, if needed. The separators between the values are a minus, another minus, a colon, and a single space between the Day and Hour. If Include_Time_Fraction is True, the integer part of Sub_Seconds*100 is suffixed to the string as a point followed by a 2-digit value.
- 82.a/2 **Discussion:** The Image provides a string in ISO 8601 format, the international standard time format. Alternative representations allowed in ISO 8601 are not supported here.
- 82.b/2 ISO 8601 allows 24:00:00 for midnight; and a seconds value of 60 for leap seconds. These are not allowed here (the routines mentioned above cannot produce those results).
- 82.c/2 **Ramification:** The fractional part is truncated, not rounded. It would be quite hard to define the result with proper rounding, as it can change all of the values of the image. Values can be rounded up by adding an appropriate constant (0.5 if Include_Time_Fraction is False, 0.005 otherwise) to the time before taking the image.
- 83/2 **function** Value (Date : String;
 Time_Zone : Time_Zones.Time_Offset := 0) **return** Time;
- 84/2 {AI95-00351-01} Returns a Time value for the image given as Date, relative to the given time zone. Constraint_Error is raised if the string is not formatted as described for Image, or the function cannot interpret the given string as a Time value.
- 84.a/3 **Discussion:** {AI05-0005-1} The intent is that the implementation enforce the same range rules on the string as the appropriate function Time_Of, except for the hour, so “cannot interpret the given string as a Time value” happens when one of the values is out of the required range. For example, "2005-08-31 24:00:00" should raise Constraint_Error (the hour is out of range).

- function** Image (Elapsed_Time : Duration; Include_Time_Fraction : Boolean := False) **return** String; 85/2
- {AI95-00351-01}* Returns a string form of the Elapsed_Time. The format is "Hour:Minute:Second", where all values are 2-digit values, including a leading zero, if needed. The separators between the values are colons. If Include_Time_Fraction is True, the integer part of Sub_Seconds*100 is suffixed to the string as a point followed by a 2-digit value. If Elapsed_Time < 0.0, the result is Image (**abs** Elapsed_Time, Include_Time_Fraction) prefixed with a minus sign. If **abs** Elapsed_Time represents 100 hours or more, the result is implementation-defined. 86/2
- Implementation defined:** The result of Calendar.Formatting.Image if its argument represents more than 100 hours. 86.a/2
- Implementation Note:** This cannot be implemented (directly) by calling Calendar.Formatting.Split, since it may be out of the range of Day_Duration, and thus the number of hours may be out of the range of Hour_Number. 86.b/2
- If a Duration value can represent more than 100 hours, the implementation will need to define a format for the return of Image. 86.c
- function** Value (Elapsed_Time : String) **return** Duration; 87/2
- {AI95-00351-01}* Returns a Duration value for the image given as Elapsed_Time. Constraint_Error is raised if the string is not formatted as described for Image, or the function cannot interpret the given string as a Duration value. 88/2
- Discussion:** The intent is that the implementation enforce the same range rules on the string as the appropriate function Time_Of, except for the hour, so “cannot interpret the given string as a Time value” happens when one of the values is out of the required range. For example, "10:23:60" should raise Constraint_Error (the seconds value is out of range). 88.a/2
- Implementation Advice*
- {AI95-00351-01}* An implementation should support leap seconds if the target system supports them. If leap seconds are not supported, Difference should return zero for Leap_Seconds, Split should return False for Leap_Second, and Time_Of should raise Time_Error if Leap_Second is True. 89/2
- Implementation Advice:** Leap seconds should be supported if the target system supports them. Otherwise, operations in Calendar.Formatting should return results consistent with no leap seconds. 89.a/2
- Discussion:** An implementation can always support leap seconds when the target system does not; indeed, this isn't particularly hard (all that is required is a table of when leap seconds were inserted). As such, leap second support isn't “impossible or impractical” in the sense of 1.1.3. However, for some purposes, it may be important to follow the target system's lack of leap second support (if the target is a GPS satellite, which does not use leap seconds, leap second support would be a handicap to work around). Thus, this Implementation Advice should be read as giving permission to not support leap seconds on target systems that don't support leap seconds. Implementers should use the needs of their customers to determine whether or not support leap seconds on such targets. 89.b/2
- NOTES
- 38 *{AI95-00351-01}* The implementation-defined time zone of package Calendar may, but need not, be the local time zone. UTC_Time_Offset always returns the difference relative to the implementation-defined time zone of package Calendar. If UTC_Time_Offset does not raise Unknown_Zone_Error, UTC time can be safely calculated (within the accuracy of the underlying time-base). 90/2
- Discussion:** *{AI95-00351-01}* The time in the time zone known as Greenwich Mean Time (GMT) is generally very close to UTC time; for most purposes they can be treated the same. GMT is the time based on the rotation of the Earth; UTC is the time based on atomic clocks, with leap seconds periodically inserted to realign with GMT (because most human activities depend on the rotation of the Earth). At any point in time, there will be a sub-second difference between GMT and UTC. 90.a/2
- 39 *{AI95-00351-01}* Calling Split on the results of subtracting Duration(UTC_Time_Offset*60) from Clock provides the components (hours, minutes, and so on) of the UTC time. In the United States, for example, UTC_Time_Offset will generally be negative. 91/2
- Discussion:** This is an illustration to help specify the value of UTC_Time_Offset. A user should pass UTC_Time_Offset as the Time_Zone parameter of Split, rather than trying to make the above calculation. 91.a/2

Extensions to Ada 95

- 91.b/2 {AI95-00351-01} {AI95-00428-01} Packages Calendar.Time_Zones, Calendar.Arithmetic, and Calendar.Formatting are new.

Inconsistencies With Ada 2005

- 91.c/3 {AI05-0238-1} **Correction:** Defined that Split for Seconds raises Time_Error for a value of exactly 86400.0, rather than breaking some invariant or raising some other exception. Ada 2005 left this unspecified; a program that depended on what some implementation does might break, but such a program is not portable anyway.

Wording Changes from Ada 2005

- 91.d/3 {AI05-0119-1} **Correction:** Clarified the sign of UTC_Time_Offset.

9.7 Select Statements

- 1 [There are four forms of the `select_statement`. One form provides a selective wait for one or more `select_alternatives`. Two provide timed and conditional entry calls. The fourth provides asynchronous transfer of control.]

Syntax

- 2 `select_statement ::=`
 `selective_accept`
 | `timed_entry_call`
 | `conditional_entry_call`
 | `asynchronous_select`

Examples

- 3 *Example of a select statement:*

- 4 `select`
 `accept Driver_Awake_Signal;`
 `or`
 `delay 30.0*Seconds;`
 `Stop_The_Train;`
 `end select;`

Extensions to Ada 83

- 4.a `Asynchronous_select` is new.

9.7.1 Selective Accept

- 1 [This form of the `select_statement` allows a combination of waiting for, and selecting from, one or more alternatives. The selection may depend on conditions associated with each alternative of the `selective_accept`.]

Syntax

selective_accept ::=	2
select	
[guard]	
select_alternative	
{ or	
[guard]	
select_alternative }	
[else	
sequence_of_statements]	
end select ;	
guard ::= when condition =>	3
select_alternative ::=	4
accept_alternative	
delay_alternative	
terminate_alternative	
accept_alternative ::=	5
accept_statement [sequence_of_statements]	
delay_alternative ::=	6
delay_statement [sequence_of_statements]	
terminate_alternative ::= terminate ;	7
A selective_accept shall contain at least one accept_alternative. In addition, it can contain:	8
• a terminate_alternative (only one); or	9
• one or more delay_alternatives; or	10
• an <i>else part</i> (the reserved word else followed by a sequence_of_statements).	11
These three possibilities are mutually exclusive.	12

Legality Rules

If a selective_accept contains more than one delay_alternative, then all shall be delay_relative_statements, or all shall be delay_until_statements for the same time type. 13

Reason: This simplifies the implementation and the description of the semantics. 13.a

Dynamic Semantics

A select_alternative is said to be *open* if it is not immediately preceded by a guard, or if the condition of its guard evaluates to True. It is said to be *closed* otherwise. 14

For the execution of a selective_accept, any guard conditions are evaluated; open alternatives are thus determined. For an open delay_alternative, the delay_expression is also evaluated. Similarly, for an open accept_alternative for an entry of a family, the entry_index is also evaluated. These evaluations are performed in an arbitrary order, except that a delay_expression or entry_index is not evaluated until after evaluating the corresponding condition, if any. Selection and execution of one open alternative, or of the else part, then completes the execution of the selective_accept; the rules for this selection are described below. 15

Open accept_alternatives are first considered. Selection of one such alternative takes place immediately if the corresponding entry already has queued calls. If several alternatives can thus be selected, one of them is selected according to the entry queuing policy in effect (see 9.5.3 and D.4). When such an alternative is selected, the selected call is removed from its entry queue and the handled_sequence_of_ 16

statements (if any) of the corresponding `accept_statement` is executed; after the rendezvous completes any subsequent `sequence_of_statements` of the alternative is executed. If no selection is immediately possible (in the above sense) and there is no else part, the task blocks until an open alternative can be selected.

17 Selection of the other forms of alternative or of an else part is performed as follows:

- 18 • An open `delay_alternative` is selected when its expiration time is reached if no `accept_`-`alternative` or other `delay_alternative` can be selected prior to the expiration time. If several `delay_alternatives` have this same expiration time, one of them is selected according to the queuing policy in effect (see D.4); the default queuing policy chooses arbitrarily among the `delay_alternatives` whose expiration time has passed.
- 19 • The else part is selected and its `sequence_of_statements` is executed if no `accept_alternative` can immediately be selected; in particular, if all alternatives are closed.
- 20/3 • *{AI05-0299-1}* An open `terminate_alternative` is selected if the conditions stated at the end of subclause 9.3 are satisfied.

20.a **Ramification:** In the absence of a `requeue_statement`, the conditions stated are such that a `terminate_alternative` cannot be selected while there is a queued entry call for any entry of the task. In the presence of `requeues` from a task to one of its subtasks, it is possible that when a `terminate_alternative` of the subtask is selected, `requeued` calls (for closed entries only) might still be queued on some entry of the subtask. `Tasking_Error` will be propagated to such callers, as is usual when a task completes while queued callers remain.

21 The exception `Program_Error` is raised if all alternatives are closed and there is no else part.

NOTES

22 40 A `selective_accept` is allowed to have several open `delay_alternatives`. A `selective_accept` is allowed to have several open `accept_alternatives` for the same entry.

Examples

23 *Example of a task body with a selective accept:*

```
24  task body Server is
      Current_Work_Item : Work_Item;
  begin
      loop
          select
              accept Next_Work_Item(WI : in Work_Item) do
                  Current_Work_Item := WI;
              end;
              Process_Work_Item(Current_Work_Item);
          or
              accept Shut_Down;
              exit;           -- Premature shut down requested
          or
              terminate;    -- Normal shutdown at end of scope
          end select;
      end loop;
  end Server;
```

Wording Changes from Ada 83

24.a The name of `selective_wait` was changed to `selective_accept` to better describe what is being waited for. We kept `select_alternative` as is, because `selective_accept_alternative` was too easily confused with `accept_alternative`.

9.7.2 Timed Entry Calls

1/2 *{AI95-00345-01}* [A `timed_entry_call` issues an entry call that is cancelled if the call (or a `requeue-with-abort` of the call) is not selected before the expiration time is reached. A procedure call may appear rather than an entry call for cases where the procedure might be implemented by an entry.]

Syntax

<pre> timed_entry_call ::= select entry_call_alternative or delay_alternative end select; </pre>	2
<pre> {AI95-00345-01} entry_call_alternative ::= procedure_or_entry_call [sequence_of_statements] </pre>	3/2
<pre> {AI95-00345-01} procedure_or_entry_call ::= procedure_call_statement entry_call_statement </pre>	3.1/2

Legality Rules

{AI95-00345-01} If a `procedure_call_statement` is used for a `procedure_or_entry_call`, the `procedure_name` or `procedure_prefix` of the `procedure_call_statement` shall statically denote an entry renamed as a procedure or (a view of) a primitive subprogram of a limited interface whose first parameter is a controlling parameter (see 3.9.2). 3.2/2

Reason: This would be a confusing way to call a procedure, so we only allow it when it is possible that the procedure is actually an entry. We could have allowed formal subprograms here, but we didn't because we'd have to allow all formal subprograms, and it would increase the difficulty of generic code sharing. 3.a/2

We say “statically denotes” because an access-to-subprogram cannot be primitive, and we don't have anything like access-to-entry. So only names of entries or procedures are possible. 3.b/2

Dynamic Semantics

{AI95-00345-01} For the execution of a `timed_entry_call`, the `entry_name`, `procedure_name`, or `procedure_prefix`, and any actual parameters are evaluated, as for a simple entry call (see 9.5.3) or procedure call (see 6.4). The expiration time (see 9.6) for the call is determined by evaluating the `delay_expression` of the `delay_alternative`. If the call is an entry call or a call on a procedure implemented by an entry, the entry call is then issued. Otherwise, the call proceeds as described in 6.4 for a procedure call, followed by the `sequence_of_statements` of the `entry_call_alternative`; the `sequence_of_statements` of the `delay_alternative` is ignored. 4/2

If the call is queued (including due to a `requeue-with-abort`), and not selected before the expiration time is reached, an attempt to cancel the call is made. If the call completes due to the cancellation, the optional `sequence_of_statements` of the `delay_alternative` is executed; if the entry call completes normally, the optional `sequence_of_statements` of the `entry_call_alternative` is executed. 5

This paragraph was deleted. {AI95-00345-01} 5.a/2

Examples

Example of a timed entry call: 6

```

select
  Controller.Request (Medium) (Some_Item);
or
  delay 45.0;
  -- controller too busy, try something else
end select;

```

7

Wording Changes from Ada 83

{AI05-0299-1} This subclause comes before the one for Conditional Entry Calls, so we can define conditional entry calls in terms of timed entry calls. 7.a/3

Incompatibilities With Ada 95

- 7.b/3 {AI95-00345-01} {AI05-0005-1} A procedure call can be used as the `entry_call_alternative` in a timed or conditional entry call, if the procedure might actually be an entry. Since the fact that something is an entry could be used in resolving these calls in Ada 95, it is possible for timed or conditional entry calls that resolved in Ada 95 to be ambiguous in Ada 2005. That could happen if both an entry and procedure with the same name and profile exist, which should be rare.

9.7.3 Conditional Entry Calls

- 1/2 {AI95-00345-01} [A `conditional_entry_call` issues an entry call that is then cancelled if it is not selected immediately (or if a `requeue-with-abort` of the call is not selected immediately). A procedure call may appear rather than an entry call for cases where the procedure might be implemented by an entry.]

- 1.a **To be honest:** In the case of an entry call on a protected object, it is OK if the entry is closed at the start of the corresponding protected action, so long as it opens and the call is selected before the end of that protected action (due to changes in the `Count` attribute).

Syntax

```
2 conditional_entry_call ::=
  select
  entry_call_alternative
  else
  sequence_of_statements
  end select;
```

Dynamic Semantics

- 3 The execution of a `conditional_entry_call` is defined to be equivalent to the execution of a `timed_entry_call` with a `delay_alternative` specifying an immediate expiration time and the same `sequence_of_statements` as given after the reserved word **else**.

NOTES

- 4 41 A `conditional_entry_call` may briefly increase the `Count` attribute of the entry, even if the conditional call is not selected.

Examples

- 5 *Example of a conditional entry call:*

```
6 procedure Spin(R : in Resource) is
  begin
    loop
      select
        R.Seize;
        return;
      else
        null; -- busy waiting
      end select;
    end loop;
  end;
```

Wording Changes from Ada 83

- 6.a/3 {AI05-0299-1} This subclause comes after the one for Timed Entry Calls, so we can define conditional entry calls in terms of timed entry calls. We do that so that an "expiration time" is defined for both, thereby simplifying the definition of what happens on a `requeue-with-abort`.

9.7.4 Asynchronous Transfer of Control

- 1 [An asynchronous `select_statement` provides asynchronous transfer of control upon completion of an entry call or the expiration of a delay.]

Syntax

<code>asynchronous_select ::=</code>	2
select	
<i>triggering_alternative</i>	
then abort	
<i>abortable_part</i>	
end select;	
<code>triggering_alternative ::= triggering_statement [sequence_of_statements]</code>	3
<code>{AI95-00345-01} triggering_statement ::= procedure_or_entry_call delay_statement</code>	4/2
<code>abortable_part ::= sequence_of_statements</code>	5

Dynamic Semantics

`{AI95-00345-01}` For the execution of an `asynchronous_select` whose `triggering_statement` is a `procedure_or_entry_call`, the `entry_name`, `procedure_name`, or `procedure_prefix`, and actual parameters are evaluated as for a simple entry call (see 9.5.3) or procedure call (see 6.4). If the call is an entry call or a call on a procedure implemented by an entry, the entry call is issued. If the entry call is queued (or requeued-with-abort), then the `abortable_part` is executed. [If the entry call is selected immediately, and never requeued-with-abort, then the `abortable_part` is never started.] If the call is on a procedure that is not implemented by an entry, the call proceeds as described in 6.4, followed by the `sequence_of_statements` of the `triggering_alternative`; the `abortable_part` is never started]. 6/2

For the execution of an `asynchronous_select` whose `triggering_statement` is a `delay_statement`, the `delay_expression` is evaluated and the expiration time is determined, as for a normal `delay_statement`. If the expiration time has not already passed, the `abortable_part` is executed. 7

If the `abortable_part` completes and is left prior to completion of the `triggering_statement`, an attempt to cancel the `triggering_statement` is made. If the attempt to cancel succeeds (see 9.5.3 and 9.6), the `asynchronous_select` is complete. 8

If the `triggering_statement` completes other than due to cancellation, the `abortable_part` is aborted (if started but not yet completed — see 9.8). If the `triggering_statement` completes normally, the optional `sequence_of_statements` of the `triggering_alternative` is executed after the `abortable_part` is left. 9

Discussion: We currently don't specify when the by-copy [**in**] **out** parameters are assigned back into the actuals. We considered requiring that to happen after the `abortable_part` is left. However, that doesn't seem useful enough to justify possibly overspecifying the implementation approach, since some of the parameters are passed by reference anyway. 9.a

In an earlier description, we required that the `sequence_of_statements` of the `triggering_alternative` execute after aborting the `abortable_part`, but before waiting for it to complete and finalize, to provide more rapid response to the triggering event in case the finalization was unbounded. However, various reviewers felt that this created unnecessary complexity in the description, and a potential for undesirable concurrency (and nondeterminism) within a single task. We have now reverted to simpler, more deterministic semantics, but anticipate that further discussion of this issue might be appropriate during subsequent reviews. One possibility is to leave this area implementation defined, so as to encourage experimentation. The user would then have to assume the worst about what kinds of actions are appropriate for the `sequence_of_statements` of the `triggering_alternative` to achieve portability. 9.b

Examples

10 Example of a main command loop for a command interpreter:

```
11  loop
    select
      Terminal.Wait_For_Interrupt;
      Put_Line("Interrupted");
    then abort
      -- This will be abandoned upon terminal interrupt
      Put_Line("-> ");
      Get_Line(Command, Last);
      Process_Command(Command(1..Last));
    end select;
  end loop;
```

12 Example of a time-limited calculation:

```
13  select
    delay 5.0;
    Put_Line("Calculation does not converge");
  then abort
    -- This calculation should finish in 5.0 seconds;
    -- if not, it is assumed to diverge.
    Horribly_Complicated_Recursive_Function(X, Y);
  end select;
```

Extensions to Ada 83

13.a Asynchronous_select is new.

Extensions to Ada 95

13.b/2 {AI95-00345-01} A procedure can be used as the triggering_statement of an asynchronous_select, if the procedure might actually be an entry.

9.8 Abort of a Task - Abort of a Sequence of Statements

1 [An abort_statement causes one or more tasks to become abnormal, thus preventing any further interaction with such tasks. The completion of the triggering_statement of an asynchronous_select causes a sequence_of_statements to be aborted.]

Syntax

```
2  abort_statement ::= abort task_name {, task_name};
```

Name Resolution Rules

3 Each task_name is expected to be of any task type[; they need not all be of the same task type.]

Dynamic Semantics

4 For the execution of an abort_statement, the given task_names are evaluated in an arbitrary order. Each named task is then aborted, which consists of making the task abnormal and aborting the execution of the corresponding task_body, unless it is already completed.

4.a/2 **Ramification:** {AI95-00114-01} Note that aborting those tasks is not defined to be an abort-deferred operation. Therefore, if one of the named tasks is the task executing the abort_statement, or if the task executing the abort_statement depends on one of the named tasks, then it is possible for the execution of the abort_statement to be aborted, thus leaving some of the tasks un-aborted. This allows the implementation to use either a sequence of calls to an “abort task” run-time system primitive, or a single call to an “abort list of tasks” run-time system primitive.

5 When the execution of a construct is aborted (including that of a task_body or of a sequence_of_statements), the execution of every construct included within the aborted execution is also aborted, except for executions included within the execution of an abort-deferred operation; the execution of an

abort-deferred operation continues to completion without being affected by the abort; the following are the abort-deferred operations:

- a protected action; 6
- waiting for an entry call to complete (after having initiated the attempt to cancel it — see below); 7
- waiting for the termination of dependent tasks; 8
- the execution of an Initialize procedure as the last step of the default initialization of a controlled object; 9
- the execution of a Finalize procedure as part of the finalization of a controlled object; 10
- an assignment operation to an object with a controlled part. 11

[The last three of these are discussed further in 7.6.] 12

Reason: Deferring abort during Initialize and finalization allows, for example, the result of an allocator performed in an Initialize operation to be assigned into an access object without being interrupted in the middle, which would cause storage leaks. For an object with several controlled parts, each individual Initialize is abort-deferred. Note that there is generally no semantic difference between making each Finalize abort-deferred, versus making a group of them abort-deferred, because if the task gets aborted, the first thing it will do is complete any remaining finalizations. Individual objects are finalized prior to an assignment operation (if nonlimited controlled) and as part of Unchecked_Deallocation. 12.a

Ramification: Abort is deferred during the entire assignment operation to an object with a controlled part, even if only some subcomponents are controlled. Note that this says "assignment operation," not "assignment_statement." Explicit calls to Initialize, Finalize, or Adjust are not abort-deferred. 12.b

When a master is aborted, all tasks that depend on that master are aborted. 13

The order in which tasks become abnormal as the result of an `abort_statement` or the abort of a `sequence_of_statements` is not specified by the language. 14

If the execution of an entry call is aborted, an immediate attempt is made to cancel the entry call (see 9.5.3). If the execution of a construct is aborted at a time when the execution is blocked, other than for an entry call, at a point that is outside the execution of an abort-deferred operation, then the execution of the construct completes immediately. For an abort due to an `abort_statement`, these immediate effects occur before the execution of the `abort_statement` completes. Other than for these immediate cases, the execution of a construct that is aborted does not necessarily complete before the `abort_statement` completes. However, the execution of the aborted construct completes no later than its next *abort completion point* (if any) that occurs outside of an abort-deferred operation; the following are abort completion points for an execution: 15

- the point where the execution initiates the activation of another task; 16
- the end of the activation of a task; 17
- the start or end of the execution of an entry call, `accept_statement`, `delay_statement`, or `abort_statement`; 18

Ramification: Although the abort completion point doesn't occur until the end of the entry call or `delay_statement`, these operations might be cut short because an abort attempts to cancel them. 18.a

- the start of the execution of a `select_statement`, or of the `sequence_of_statements` of an `exception_handler`. 19

Reason: The start of an `exception_handler` is considered an abort completion point simply because it is easy for an implementation to check at such points. 19.a

Implementation Note: Implementations may of course check for abort more often than at each abort completion point; ideally, a fully preemptive implementation of abort will be provided. If preemptive abort is not supported in a given environment, then supporting the checking for abort as part of subprogram calls and loop iterations might be a useful option. 19.b

Bounded (Run-Time) Errors

- 20/3 {AI05-0264-1} An attempt to execute an `asynchronous_select` as part of the execution of an abort-deferred operation is a bounded error. Similarly, an attempt to create a task that depends on a master that is included entirely within the execution of an abort-deferred operation is a bounded error. In both cases, `Program_Error` is raised if the error is detected by the implementation; otherwise, the operations proceed as they would outside an abort-deferred operation, except that an abort of the `abortable_part` or the created task might or might not have an effect.
- 20.a **Reason:** An `asynchronous_select` relies on an abort of the `abortable_part` to effect the asynchronous transfer of control. For an `asynchronous_select` within an abort-deferred operation, the abort might have no effect.
- 20.b Creating a task dependent on a master included within an abort-deferred operation is considered an error, because such tasks could be aborted while the abort-deferred operation was still progressing, undermining the purpose of abort-deferral. Alternatively, we could say that such tasks are abort-deferred for their entire execution, but that seems too easy to abuse. Note that task creation is already a bounded error in protected actions, so this additional rule only applies to local task creation as part of Initialize, Finalize, or Adjust.

Erroneous Execution

- 21 If an assignment operation completes prematurely due to an abort, the assignment is said to be *disrupted*; the target of the assignment or its parts can become abnormal, and certain subsequent uses of the object can be erroneous, as explained in 13.9.1.

NOTES

- 22 42 An `abort_statement` should be used only in situations requiring unconditional termination.
- 23 43 A task is allowed to abort any task it can name, including itself.
- 24 44 Additional requirements associated with abort are given in D.6, “Preemptive Abort”.

Wording Changes from Ada 83

- 24.a/3 {AI05-0299-1} This subclause has been rewritten to accommodate the concept of aborting the execution of a construct, rather than just of a task.

9.9 Task and Entry Attributes

Dynamic Semantics

- 1 For a prefix `T` that is of a task type [(after any implicit dereference)], the following attributes are defined:
- 2 `T'Callable` Yields the value `True` when the task denoted by `T` is *callable*, and `False` otherwise; a task is callable unless it is completed or abnormal. The value of this attribute is of the predefined type `Boolean`.
- 3 `T'Terminated`
Yields the value `True` if the task denoted by `T` is terminated, and `False` otherwise. The value of this attribute is of the predefined type `Boolean`.
- 4 For a prefix `E` that denotes an entry of a task or protected unit, the following attribute is defined. This attribute is only allowed within the body of the task or protected unit, but excluding, in the case of an entry of a task unit, within any program unit that is, itself, inner to the body of the task unit.
- 5 `E'Count` Yields the number of calls presently queued on the entry `E` of the current instance of the unit. The value of this attribute is of the type *universal_integer*.

NOTES

- 6 45 For the `Count` attribute, the entry can be either a single entry or an entry of a family. The name of the entry or entry family can be either a `direct_name` or an expanded name.
- 7 46 Within task units, algorithms interrogating the attribute `E'Count` should take precautions to allow for the increase of the value of this attribute for incoming entry calls, and its decrease, for example with `timed_entry_calls`. Also, a `conditional_entry_call` may briefly increase this value, even if the conditional call is not accepted.

47 Within protected units, algorithms interrogating the attribute E'Count in the entry_barrier for the entry E should take precautions to allow for the evaluation of the condition of the barrier both before and after queuing a given caller. 8

9.10 Shared Variables

Static Semantics

{AI05-0009-1} {AI05-0201-1} {AI05-0229-1} {AI05-0295-1} If two different objects, including nonoverlapping parts of the same object, are *independently addressable*, they can be manipulated concurrently by two different tasks without synchronization. Any two nonoverlapping objects are independently addressable if either object is specified as independently addressable (see C.6). Otherwise, two nonoverlapping objects are independently addressable except when they are both parts of a composite object for which a nonconfirming value is specified for any of the following representation aspects: (record) Layout, Component_Size, Pack, Atomic, or Convention; in this case it is unspecified whether the parts are independently addressable. 1/3

This paragraph was deleted. 1.a/3

Implementation Note: {AI05-0229-1} Independent addressability is the only high level semantic effect of aspect Pack. If two objects are independently addressable, the implementation should allocate them in such a way that each can be written by the hardware without writing the other. For example, unless the user asks for it, it is generally not feasible to choose a bit-packed representation on a machine without an atomic bit field insertion instruction, because there might be tasks that update neighboring subcomponents concurrently, and locking operations on all subcomponents is generally not a good idea. 1.b/3

{AI05-0229-1} Even if Pack or one of the other above-mentioned aspects is specified, subcomponents should still be updated independently if the hardware efficiently supports it. 1.c/3

Ramification: {AI05-0009-1} {AI05-0201-1} An atomic object (including atomic components) is always independently addressable from any other nonoverlapping object. Any aspect_specification or representation item which would prevent this from being true should be rejected, notwithstanding what this Standard says elsewhere. Note, however, that the components of an atomic object are not necessarily atomic. 1.d/3

Dynamic Semantics

[Separate tasks normally proceed independently and concurrently with one another. However, task interactions can be used to synchronize the actions of two or more tasks to allow, for example, meaningful communication by the direct updating and reading of variables shared between the tasks.] The actions of two different tasks are synchronized in this sense when an action of one task *signals* an action of the other task; an action A1 is defined to signal an action A2 under the following circumstances: 2

- If A1 and A2 are part of the execution of the same task, and the language rules require A1 to be performed before A2; 3
- If A1 is the action of an activator that initiates the activation of a task, and A2 is part of the execution of the task that is activated; 4
- If A1 is part of the activation of a task, and A2 is the action of waiting for completion of the activation; 5
- If A1 is part of the execution of a task, and A2 is the action of waiting for the termination of the task; 6
- {8652/0031} {AI95-00118-01} {AI05-0072-1} If A1 is the termination of a task T, and A2 is either an evaluation of the expression T'Terminated that results in True, or a call to Ada.Task_Identification.Is_Terminated with an actual parameter that identifies T and a result of True (see C.7.1); 6.1/3
- {AI05-0262-1} If A1 is the action of issuing an entry call, and A2 is part of the corresponding execution of the appropriate entry_body or accept_statement; 7/3

- 7.a **Ramification:** Evaluating the `entry_index` of an `accept_statement` is not synchronized with a corresponding entry call, nor is evaluating the entry barrier of an `entry_body`.
- 8 • If A1 is part of the execution of an `accept_statement` or `entry_body`, and A2 is the action of returning from the corresponding entry call;
- 9 • If A1 is part of the execution of a protected procedure body or `entry_body` for a given protected object, and A2 is part of a later execution of an `entry_body` for the same protected object;
- 9.a **Reason:** The underlying principle here is that for one action to “signal” a second, the second action has to follow a potentially blocking operation, whose blocking is dependent on the first action in some way. Protected procedures are not potentially blocking, so they can only be “signalers,” they cannot be signaled.
- 9.b **Ramification:** Protected subprogram calls are not defined to signal one another, which means that such calls alone cannot be used to synchronize access to shared data outside of a protected object.
- 9.c **Reason:** The point of this distinction is so that on multiprocessors with inconsistent caches, the caches only need to be refreshed at the beginning of an entry body, and forced out at the end of an entry body or protected procedure that leaves an entry open. Protected function calls, and protected subprogram calls for entryless protected objects do not require full cache consistency. Entryless protected objects are intended to be treated roughly like atomic objects — each operation is indivisible with respect to other operations (unless both are reads), but such operations cannot be used to synchronize access to other nonvolatile shared variables.
- 10 • If A1 signals some action that in turn signals A2.

Erroneous Execution

- 11 Given an action of assigning to an object, and an action of reading or updating a part of the same object (or of a neighboring object if the two are not independently addressable), then the execution of the actions is erroneous unless the actions are *sequential*. Two actions are sequential if one of the following is true:
- 12 • One action signals the other;
- 13 • Both actions occur as part of the execution of the same task;
- 13.a **Reason:** Any two actions of the same task are sequential, even if one does not signal the other because they can be executed in an “arbitrary” (but necessarily equivalent to some “sequential”) order.
- 14 • Both actions occur as part of protected actions on the same protected object, and at most one of the actions is part of a call on a protected function of the protected object.
- 14.a **Reason:** Because actions within protected actions do not always imply signaling, we have to mention them here explicitly to make sure that actions occurring within different protected actions of the same protected object are sequential with respect to one another (unless both are part of calls on protected functions).
- 14.b **Ramification:** It doesn't matter whether or not the variable being assigned is actually a subcomponent of the protected object; globals can be safely updated from within the bodies of protected procedures or entries.
- 15/3 *{AI05-0229-1}* Aspect `Atomic` or aspect `Atomic_Components` may also be specified to ensure that certain reads and updates are sequential — see C.6.
- 15.a **Ramification:** If two actions are “sequential” it is known that their executions don't overlap in time, but it is not necessarily specified which occurs first. For example, all actions of a single task are sequential, even though the exact order of execution is not fully specified for all constructs.
- 15.b **Discussion:** Note that if two assignments to the same variable are sequential, but neither signals the other, then the program is not erroneous, but it is not specified which assignment ultimately prevails. Such a situation usually corresponds to a programming mistake, but in some (rare) cases, the order makes no difference, and for this reason this situation is not considered erroneous nor even a bounded error. In Ada 83, this was considered an “incorrect order dependence” if the “effect” of the program was affected, but “effect” was never fully defined. In Ada 95, this situation represents a potential nonportability, and a friendly compiler might want to warn the programmer about the situation, but it is not considered an error. An example where this would come up would be in gathering statistics as part of referencing some information, where the assignments associated with statistics gathering don't need to be ordered since they are just accumulating aggregate counts, sums, products, etc.

Wording Changes from Ada 95

- 15.c/2 *{8652/0031}* *{AI95-00118-01}* **Corrigendum:** Clarified that a task T2 can rely on values of variables that are updated by another task T1, if task T2 first verifies that T1'Terminated is True.

Wording Changes from Ada 2005

{AI05-0009-1} {AI05-0201-1} **Correction:** Revised the definition of independent addressability to exclude conforming representation clauses and to require that atomic and independent objects always have independent addressability. This should not change behavior that the user sees for any Ada program, so it is not an inconsistency. 15.d/3

{AI05-0072-1} **Correction:** Corrected the wording of AI95-00118-01 to actually say what was intended (as described above). 15.e/3

9.11 Example of Tasking and Synchronization

Examples

The following example defines a buffer protected object to smooth variations between the speed of output of a producing task and the speed of input of some consuming task. For instance, the producing task might have the following structure: 1

```
task Producer; 2
{AI95-00433-01} task body Producer is 3/2
  Person : Person_Name; -- see 3.10.1
begin
  loop
    ... -- simulate arrival of the next customer
    Buffer.Append_Wait(Person);
    exit when Person = null;
  end loop;
end Producer;
```

and the consuming task might have the following structure: 4

```
task Consumer; 5
{AI95-00433-01} task body Consumer is 6/2
  Person : Person_Name;
begin
  loop
    Buffer.Remove_First_Wait(Person);
    exit when Person = null;
    ... -- simulate serving a customer
  end loop;
end Consumer;
```

{AI95-00433-01} The buffer object contains an internal array of person names managed in a round-robin fashion. The array has two indices, an In_Index denoting the index for the next input person name and an Out_Index denoting the index for the next output person name. 7/2

{AI95-00433-01} The Buffer is defined as an extension of the Synchronized_Queue interface (see 3.9.4), and as such promises to implement the abstraction defined by that interface. By doing so, the Buffer can be passed to the Transfer class-wide operation defined for objects of a type covered by Queue'Class. 7.1/2

```
{AI95-00433-01} protected Buffer is new Synchronized_Queue with -- see 3.9.4 8/2
  entry Append_Wait(Person : in Person_Name);
  entry Remove_First_Wait(Person : out Person_Name);
  function Cur_Count return Natural;
  function Max_Count return Natural;
  procedure Append(Person : in Person_Name);
  procedure Remove_First(Person : out Person_Name);
private
  Pool      : Person_Name_Array(1 .. 100);
  Count     : Natural := 0;
  In_Index, Out_Index : Positive := 1;
end Buffer;
```

```

9/2      {AI95-00433-01} protected body Buffer is
        entry Append_Wait(Person : in Person_Name)
            when Count < Pool'Length is
        begin
            Append(Person);
        end Append_Wait;

9.1/2    {AI95-00433-01}    procedure Append(Person : in Person_Name) is
        begin
            if Count = Pool'Length then
                raise Queue_Error with "Buffer Full"; -- see 11.3
            end if;
            Pool(In_Index) := Person;
            In_Index      := (In_Index mod Pool'Length) + 1;
            Count         := Count + 1;
        end Append;

10/2     {AI95-00433-01}    entry Remove_First_Wait(Person : out Person_Name)
        when Count > 0 is
        begin
            Remove_First(Person);
        end Remove_First_Wait;

11/2     {AI95-00433-01}    procedure Remove_First(Person : out Person_Name) is
        begin
            if Count = 0 then
                raise Queue_Error with "Buffer Empty"; -- see 11.3
            end if;
            Person      := Pool(Out_Index);
            Out_Index   := (Out_Index mod Pool'Length) + 1;
            Count       := Count - 1;
        end Remove_First;

12/2     {AI95-00433-01}    function Cur_Count return Natural is
        begin
            return Buffer.Count;
        end Cur_Count;

13/2     {AI95-00433-01}    function Max_Count return Natural is
        begin
            return Pool'Length;
        end Max_Count;
end Buffer;

```

10 Program Structure and Compilation Issues

{AI05-0299-1} [The overall structure of programs and the facilities for separate compilation are described in this clause. A *program* is a set of *partitions*, each of which may execute in a separate address space, possibly on a separate computer. 1/3

Glossary entry: A *program* is a set of *partitions*, each of which may execute in a separate address space, possibly on a separate computer. A partition consists of a set of library units. 1.a

Glossary entry: A *partition* is a part of a program. Each partition consists of a set of library units. Each partition may run in a separate address space, possibly on a separate computer. A program may contain just one partition. A distributed program typically contains multiple partitions, which can execute concurrently. 1.b

As explained below, a partition is constructed from *library units*. Syntactically, the declaration of a library unit is a *library_item*, as is the body of a library unit. An implementation may support a concept of a *program library* (or simply, a “library”), which contains *library_items* and their subunits. Library units may be organized into a hierarchy of children, grandchildren, and so on.] 2

{AI05-0299-1} This clause has two subclasses: 10.1, “Separate Compilation” discusses compile-time issues related to separate compilation. 10.2, “Program Execution” discusses issues related to what is traditionally known as “link time” and “run time” — building and executing partitions. 3/3

Language Design Principles

We should avoid specifying details that are outside the domain of the language itself. The standard is intended (at least in part) to promote portability of Ada programs at the source level. It is not intended to standardize extra-language issues such as how one invokes the compiler (or other tools), how one's source is represented and organized, version management, the format of error messages, etc. 3.a

The rules of the language should be enforced even in the presence of separate compilation. Using separate compilation should not make a program less safe. 3.b

It should be possible to determine the legality of a compilation unit by looking only at the compilation unit itself and the compilation units upon which it depends semantically. As an example, it should be possible to analyze the legality of two compilation units in parallel if they do not depend semantically upon each other. 3.c

On the other hand, it may be necessary to look outside that set in order to generate code — this is generally true for generic instantiation and inlining, for example. Also on the other hand, it is generally necessary to look outside that set in order to check Post-Compilation Rules. 3.d

See also the “generic contract model” Language Design Principle of 12.3, “Generic Instantiation”. 3.e

Wording Changes from Ada 83

{AI05-0299-1} The clause organization mentioned above is different from that of RM83. 3.f/3

10.1 Separate Compilation

[A *program unit* is either a package, a task unit, a protected unit, a protected entry, a generic unit, or an explicitly declared subprogram other than an enumeration literal. Certain kinds of program units can be separately compiled. Alternatively, they can appear physically nested within other program units. 1

The text of a program can be submitted to the compiler in one or more compilations. Each compilation is a succession of *compilation_units*. A *compilation_unit* contains either the declaration, the body, or a renaming of a program unit.] The representation for a compilation is implementation-defined. 2

Implementation defined: The representation for a compilation. 2.a

Ramification: Some implementations might choose to make a compilation be a source (text) file. Others might allow multiple source files to be automatically concatenated to form a single compilation. Others still may represent the source in a nontextual form such as a parse tree. Note that the RM95 does not even define the concept of a source file. 2.b

Note that a protected subprogram is a subprogram, and therefore a program unit. An instance of a generic unit is a program unit. 2.c

2.d A protected entry is a program unit, but protected entries cannot be separately compiled.

3 A library unit is a separately compiled program unit, and is always a package, subprogram, or generic unit. Library units may have other (logically nested) library units as children, and may have other program units physically nested within them. A root library unit, together with its children and grandchildren and so on, form a *subsystem*.

Implementation Permissions

4 An implementation may impose implementation-defined restrictions on compilations that contain multiple `compilation_units`.

4.a **Implementation defined:** Any restrictions on compilations that contain multiple `compilation_units`.

4.b **Discussion:** For example, an implementation might disallow a compilation that contains two versions of the same compilation unit, or that contains the declarations for library packages P1 and P2, where P1 precedes P2 in the compilation but P1 has a `with_clause` that mentions P2.

Wording Changes from Ada 83

4.c The interactions between language issues and environmental issues are left open in Ada 95. The environment concept is new. In Ada 83, the concept of the program library, for example, appeared to be quite concrete, although the rules had no force, since implementations could get around them simply by defining various mappings from the concept of an Ada program library to whatever data structures were actually stored in support of separate compilation. Indeed, implementations were encouraged to do so.

4.d In RM83, it was unclear which was the official definition of “program unit.” Definitions appeared in RM83-5, 6, 7, and 9, but not 12. Placing it here seems logical, since a program unit is sort of a potential compilation unit.

10.1.1 Compilation Units - Library Units

1 [A `library_item` is a compilation unit that is the declaration, body, or renaming of a library unit. Each library unit (except Standard) has a *parent unit*, which is a library package or generic library package.] A library unit is a *child* of its parent unit. The *root* library units are the children of the predefined library package Standard.

1.a **Ramification:** Standard is a library unit.

Syntax

```

2 compilation ::= {compilation_unit}
3 compilation_unit ::=
4   context_clause library_item
5   | context_clause subunit
6 library_item ::= [private] library_unit_declaration
7   | library_unit_body
8   | [private] library_unit_renaming_declaration
9 library_unit_declaration ::=
10  subprogram_declaration | package_declaration
11  | generic_declaration   | generic_instantiation
12 library_unit_renaming_declaration ::=
13  package_renaming_declaration
14  | generic_renaming_declaration
15  | subprogram_renaming_declaration
16 library_unit_body ::= subprogram_body | package_body
17 parent_unit_name ::= name

```

{AI95-00397-01} An `overriding_indicator` is not allowed in a `subprogram_declaration`, `generic_instantiation`, or `subprogram_renaming_declaration` that declares a library unit. 8.1/2

Reason: All of the listed items syntactically include `overriding_indicator`, but a library unit can never override anything. A majority of the ARG thought that allowing **not overriding** in that case would be confusing instead of helpful. 8.a.1/2

A *library unit* is a program unit that is declared by a `library_item`. When a program unit is a library unit, the prefix “library” is used to refer to it (or “generic library” if generic), as well as to its declaration and body, as in “library procedure”, “library package_body”, or “generic library package”. The term *compilation unit* is used to refer to a `compilation_unit`. When the meaning is clear from context, the term is also used to refer to the `library_item` of a `compilation_unit` or to the `proper_body` of a subunit [(that is, the `compilation_unit` without the `context_clause` and the `separate (parent_unit_name)`)]. 9

Discussion: In this example: 9.a

```
with Ada.Text_IO;
package P is
    . . .
end P;
```

the term “compilation unit” can refer to this text: “`with Ada.Text_IO; package P is ... end P;`” or to this text: “`package P is ... end P;`”. We use this shorthand because it corresponds to common usage. 9.b

We like to use the word “unit” for declaration-plus-body things, and “item” for declaration or body separately (as in `declarative_item`). The terms “`compilation_unit`,” “compilation unit,” and “subunit” are exceptions to this rule. We considered changing “`compilation_unit`,” “compilation unit” to “`compilation_item`,” “compilation item,” respectively, but we decided not to. 9.c

The *parent declaration* of a `library_item` (and of the library unit) is the declaration denoted by the `parent_unit_name`, if any, of the `defining_program_unit_name` of the `library_item`. If there is no `parent_unit_name`, the parent declaration is the declaration of Standard, the `library_item` is a *root library_item*, and the library unit (renaming) is a *root library unit* (renaming). The declaration and body of Standard itself have no parent declaration. The *parent unit* of a `library_item` or library unit is the library unit declared by its parent declaration. 9.d

Discussion: The declaration and body of Standard are presumed to exist from the beginning of time, as it were. There is no way to actually write them, since there is no syntactic way to indicate lack of a parent. An attempt to compile a `package Standard` would result in `Standard.Standard`. 10.a

Reason: Library units (other than Standard) have “parent declarations” and “parent units”. Subunits have “parent bodies”. We didn’t bother to define the other possibilities: parent body of a library unit, parent declaration of a subunit, parent unit of a subunit. These are not needed, and might get in the way of a correct definition of “child.” 10.b

[The children of a library unit occur immediately within the declarative region of the declaration of the library unit.] The *ancestors* of a library unit are itself, its parent, its parent’s parent, and so on. [(Standard is an ancestor of every library unit.)] The *descendant* relation is the inverse of the ancestor relation. 11

Reason: These definitions are worded carefully to avoid defining subunits as children. Only library units can be children. 11.a

We use the unadorned term “ancestors” here to concisely define both “ancestor unit” and “ancestor declaration.” 11.b

A `library_unit_declaration` or a `library_unit_renaming_declaration` is *private* if the declaration is immediately preceded by the reserved word **private**; it is otherwise *public*. A library unit is private or public according to its declaration. The *public descendants* of a library unit are the library unit itself, and the public descendants of its public children. Its other descendants are *private descendants*. 12

Discussion: The first concept defined here is that a `library_item` is either public or private (not in relation to anything else — it’s just a property of the library unit). The second concept is that a `library_item` is a public descendant or private descendant of a *given ancestor*. A given `library_item` can be a public descendant of one of its ancestors, but a private descendant of some other ancestor. 12.a

A subprogram declared by a `subprogram_body` (as opposed to a `subprogram_declaration`) is always public, since the syntax rules disallow the reserved word **private** on a body. 12.b

- 12.c Note that a private library unit is a *public* descendant of itself, but a *private* descendant of its parent. This is because it is visible outside itself — its privateness means that it is not visible outside its parent.
- 12.d Private children of Standard are legal, and follow the normal rules. It is intended that implementations might have some method for taking an existing environment, and treating it as a package to be “imported” into another environment, treating children of Standard in the imported environment as children of the imported package.
- 12.e **Ramification:** Suppose we have a public library unit A, a private library unit A.B, and a public library unit A.B.C. A.B.C is a public descendant of itself and of A.B, but a private descendant of A; since A.B is private to A, we don't allow A.B.C to escape outside A either. This is similar to the situation that would occur with physical nesting, like this:
- 12.f
- ```

package A is
private
 package B is
 package C is
 end C;
 private
 end B;
 end A;

```
- 12.g Here, A.B.C is visible outside itself and outside A.B, but not outside A. (Note that this example is intended to illustrate the visibility of program units from the outside; the visibility within child units is not quite identical to that of physically nested units, since child units are nested after their parent's declaration.)
- 12.1/2 {AI95-00217-06} For each library `package_declaration` in the environment, there is an implicit declaration of a *limited view* of that library package. The limited view of a package contains:
- 12.2/3 • {AI95-00217-06} {AI05-0129-1} {AI05-0262-1} For each `package_declaration` occurring immediately within the visible part, a declaration of the limited view of that package, with the same `defining_program_unit_name`.
- 12.3/3 • {AI95-00217-06} {AI95-00326-01} {AI05-0108-1} {AI05-0129-1} {AI05-0262-1} For each `type_declaration` occurring immediately within the visible part that is not an `incomplete_type_declaration`, an incomplete view of the type with no `discriminant_part`; if the `type_declaration` is tagged, then the view is a tagged incomplete view.
- 12.g.1/3 **Reason:** {AI05-0108-1} The incomplete view of a type does not have a `discriminant_part` even if the `type_declaration` does have one. This is necessary because semantic analysis (and the associated dependence on `with_clauses`) would be necessary to determine the types of the discriminants.
- 12.g.2/3 {AI05-0129-1} No incomplete views of incomplete types are included in the limited view. The rules of 3.10.1 ensure that the completion of any visible incomplete type is declared in the same visible part, so such an incomplete view would simply be redundant.
- 12.g.3/2 **Discussion:** {AI95-00217-06} The implementation model of a limited view is that it can be determined solely from the syntax of the source of the unit, without any semantic analysis. That allows it to be created without the semantic dependences of a full unit, which is necessary for it to break mutual dependences of units.
- 12.g.4/2 **Ramification:** The limited view does not include package instances and their contents. Semantic analysis of a unit (and dependence on its `with_clauses`) would be needed to determine the contents of an instance.
- 12.4/2 The limited view of a library `package_declaration` is private if that library `package_declaration` is immediately preceded by the reserved word **private**.
- 12.5/2 [There is no syntax for declaring limited views of packages, because they are always implicit.] The implicit declaration of a limited view of a library package [is not the declaration of a library unit (the library `package_declaration` is); nonetheless, it] is a `library_item`. The implicit declaration of the limited view of a library package forms an (implicit) compilation unit whose `context_clause` is empty.
- 12.6/2 A library `package_declaration` is the completion of the declaration of its limited view.
- 12.h/2 **To be honest:** This is notwithstanding the rule in 3.11.1 that says that implicit declarations don't have completions.
- 12.i/2 **Reason:** This rule explains where to find the completions of the incomplete views defined by the limited view.

#### Legality Rules

- 13 The parent unit of a `library_item` shall be a [library] package or generic [library] package.

- If a `defining_program_unit_name` of a given declaration or body has a `parent_unit_name`, then the given declaration or body shall be a `library_item`. The body of a program unit shall be a `library_item` if and only if the declaration of the program unit is a `library_item`. In a `library_unit_renaming_declaration`, the [(old)] name shall denote a `library_item`. 14
- Discussion:** We could have allowed nested program units to be children of other program units; their semantics would make sense. We disallow them to keep things simpler and because they wouldn't be particularly useful. 14.a
- {AI95-00217-06} A `parent_unit_name` [(which can be used within a `defining_program_unit_name` of a `library_item` and in the **separate** clause of a `subunit`)], and each of its `prefixes`, shall not denote a `renaming_declaration`. [On the other hand, a name that denotes a `library_unit_renaming_declaration` is allowed in a `nonlimited_with_clause` and other places where the name of a library unit is allowed.] 15/2
- If a library package is an instance of a generic package, then every child of the library package shall either be itself an instance or be a renaming of a library unit. 16
- Discussion:** A child of an instance of a given generic unit will often be an instance of a (generic) child of the given generic unit. This is not required, however. 16.a
- Reason:** Instances are forbidden from having noninstance children for two reasons: 16.b
1. We want all source code that can depend on information from the private part of a library unit to be inside the "subsystem" rooted at the library unit. If an instance of a generic unit were allowed to have a noninstance as a child, the source code of that child might depend on information from the private part of the generic unit, even though it is outside the subsystem rooted at the generic unit. 16.c
  2. Disallowing noninstance children simplifies the description of the semantics of children of generic packages. 16.d
- {AI05-0004-1} A child of a generic library package shall either be itself a generic unit or be a renaming of some other child of the same generic unit. 17/3
- A child of a parent generic package shall be instantiated or renamed only within the declarative region of the parent generic. 18
- {AI95-00331-01} For each child *C* of some parent generic package *P*, there is a corresponding declaration *C* nested immediately within each instance of *P*. For the purposes of this rule, if a child *C* itself has a child *D*, each corresponding declaration for *C* has a corresponding child *D*. [The corresponding declaration for a child within an instance is visible only within the scope of a `with_clause` that mentions the (original) child generic unit.] 19/2
- Implementation Note:** Within the child, like anything nested in a generic unit, one can make up-level references to the current instance of its parent, and thereby gain access to the formal parameters of the parent, to the types declared in the parent, etc. This "nesting" model applies even within the `generic_formal_part` of the child, as it does for a generic child of a nongeneric unit. 19.a
- Ramification:** Suppose *P* is a generic library package, and *P.C* is a generic child of *P*. *P.C* can be instantiated inside the declarative region of *P*. Outside *P*, *P.C* can be mentioned only in a `with_clause`. Conceptually, an instance *I* of *P* is a package that has a nested generic unit called *I.C*. Mentioning *P.C* in a `with_clause` allows *I.C* to be instantiated. *I* need not be a library unit, and the instantiation of *I.C* need not be a library unit. If *I* is a library unit, and an instance of *I.C* is a child of *I*, then this instance has to be called something other than *C*. 19.b
- A library subprogram shall not override a primitive subprogram. 20
- Reason:** This prevents certain obscure anomalies. For example, if a library subprogram were to override a subprogram declared in its parent package, then in a compilation unit that depends *indirectly* on the library subprogram, the library subprogram could hide the overridden operation from all visibility, but the library subprogram itself would not be visible. 20.a
- Note that even without this rule, such subprograms would be illegal for tagged types, because of the freezing rules. 20.b
- The defining name of a function that is a compilation unit shall not be an `operator_symbol`. 21
- Reason:** Since overloading is not permitted among compilation units, it seems unlikely that it would be useful to define one as an operator. Note that a subunit could be renamed within its parent to be an operator. 21.a

## Static Semantics

22 A `subprogram_renaming_declaration` that is a `library_unit_renaming_declaration` is a renaming-as-declaration, not a renaming-as-body.

23 [There are two kinds of dependences among compilation units:]

- 24 • [The *semantic dependences* (see below) are the ones needed to check the compile-time rules across compilation unit boundaries; a compilation unit depends semantically on the other compilation units needed to determine its legality. The visibility rules are based on the semantic dependences.
- 25 • The *elaboration dependences* (see 10.2) determine the order of elaboration of `library_items`.]

25.a **Discussion:** Don't confuse these kinds of dependences with the run-time dependences among tasks and masters defined in 9.3, "Task Dependence - Termination of Tasks".

26/2 {AI95-00217-06} A `library_item` depends semantically upon its parent declaration. A subunit depends semantically upon its parent body. A `library_unit_body` depends semantically upon the corresponding `library_unit_declaration`, if any. The declaration of the limited view of a library package depends semantically upon the declaration of the limited view of its parent. The declaration of a library package depends semantically upon the declaration of its limited view. A compilation unit depends semantically upon each `library_item` mentioned in a `with_clause` of the compilation unit. In addition, if a given compilation unit contains an `attribute_reference` of a type defined in another compilation unit, then the given compilation unit depends semantically upon the other compilation unit. The semantic dependence relationship is transitive.

26.a **Discussion:** The "if any" in the third sentence is necessary because library subprograms are not required to have a `subprogram_declaration`.

26.b **To be honest:** If a given compilation unit contains a `choice_parameter_specification`, then the given compilation unit depends semantically upon the declaration of `Ada.Exceptions`.

26.c If a given compilation unit contains a `pragma` with an argument of a type defined in another compilation unit, then the given compilation unit depends semantically upon the other compilation unit.

26.d **Discussion:** For example, a compilation unit containing `X'Address` depends semantically upon the declaration of package `System`.

26.e For the `Address` attribute, this fixes a hole in Ada 83. Note that in almost all cases, the dependence will need to exist due to `with_clauses`, even without this rule. Hence, the rule has very little effect on programmers.

26.f Note that the semantic dependence does not have the same effect as a `with_clause`; in order to denote a declaration in one of those packages, a `with_clause` will generally be needed.

26.g Note that no special rule is needed for an `attribute_definition_clause`, since an expression after `use` will require semantic dependence upon the compilation unit containing the `type_declaration` of interest.

26.h/2 {AI95-00217-06} Unlike a full view of a package, a limited view does not depend semantically on units mentioned in `with_clauses` of the `compilation_unit` that defines the package. Formally, this is achieved by saying that the limited view has an empty `context_clause`. This is necessary so that they can be useful for their intended purpose: allowing mutual dependences between packages. The lack of semantic dependence limits the contents of a limited view to the items that can be determined solely from the syntax of the source of the package, without any semantic analysis. That allows it to be created without the semantic dependences of a full package.

## Dynamic Semantics

26.1/2 {AI95-00217-06} The elaboration of the declaration of the limited view of a package has no effect.

## NOTES

27 1 A simple program may consist of a single compilation unit. A compilation need not have any compilation units; for example, its text can consist of pragmas.

27.a **Ramification:** Such pragmas cannot have any arguments that are names, by a previous rule of this subclause. A compilation can even be entirely empty, which is probably not useful.

27.b Some interesting properties of the three kinds of dependence: The elaboration dependences also include the semantic dependences, except that subunits are taken together with their parents. The semantic dependences partly determine the

order in which the compilation units appear in the environment at compile time. At run time, the order is partly determined by the elaboration dependences.

The model whereby a child is inside its parent's declarative region, after the parent's declaration, as explained in 8.1, has the following ramifications: 27.c

- The restrictions on “early” use of a private type (RM83-7.4.1(4)) or a deferred constant (RM83-7.4.3(2)) do not apply to uses in child units, because they follow the full declaration. 27.d
- A library subprogram is never primitive, even if its profile includes a type declared immediately within the parent's `package_specification`, because the child is not declared immediately within the same `package_specification` as the type (so it doesn't declare a new primitive subprogram), and because the child is forbidden from overriding an old primitive subprogram. It is immediately within the same declarative region, but not the same `package_specification`. Thus, for a tagged type, it is not possible to call a child subprogram in a dispatching manner. (This is also forbidden by the freezing rules.) Similarly, it is not possible for the user to declare primitive subprograms of the types declared in the declaration of Standard, such as Integer (even if the rules were changed to allow a library unit whose name is an operator symbol). 27.e
- When the parent unit is “used” the simple names of the with'd child units are directly visible (see 8.4, “Use Clauses”). 27.f
- When a parent body with's its own child, the defining name of the child is directly visible, and the parent body is not allowed to include a declaration of a homograph of the child unit immediately within the `declarative_part` of the body (RM83-8.3(17)). 27.g

Note that “declaration of a library unit” is different from “`library_unit_declaration`” — the former includes `subprogram_body`. Also, we sometimes really mean “declaration of a view of a library unit”, which includes `library_unit_renaming_declarations`. 27.h

The visibility rules generally imply that the renamed view of a `library_unit_renaming_declaration` has to be mentioned in a `with_clause` of the `library_unit_renaming_declaration`. 27.i

**To be honest:** The real rule is that the renamed library unit has to be visible in the `library_unit_renaming_declaration`. 27.j

**Reason:** In most cases, “has to be visible” means there has to be a `with_clause`. However, it is possible in obscure cases to avoid the need for a `with_clause`; in particular, a compilation unit such as “`package P.Q renames P;`” is legal with no `with_clauses` (though not particularly interesting). ASCII is physically nested in Standard, and so is not a library unit, and cannot be renamed as a library unit. 27.k

2 The designator of a library function cannot be an `operator_symbol`, but a nonlibrary `renaming_declaration` is allowed to rename a library function as an operator. Within a partition, two library subprograms are required to have distinct names and hence cannot overload each other. However, `renaming_declarations` are allowed to define overloaded names for such subprograms, and a locally declared subprogram is allowed to overload a library subprogram. The expanded name Standard.L can be used to denote a root library unit L (unless the declaration of Standard is hidden) since root library unit declarations occur immediately within the declarative region of package Standard. 28

#### Examples

#### Examples of library units:

```

package Rational_Numbers.IO is -- public child of Rational_Numbers, see 7.1
 procedure Put(R : in Rational);
 procedure Get(R : out Rational);
end Rational_Numbers.IO;
30

private procedure Rational_Numbers.Reduce(R : in out Rational);
 -- private child of Rational_Numbers
31

with Rational_Numbers.Reduce; -- refer to a private child
package body Rational_Numbers is
 ...
end Rational_Numbers;
32

with Rational_Numbers.IO; use Rational_Numbers;
with Ada.Text_io; -- see A.10
procedure Main is -- a root library procedure
 R : Rational;
begin
 R := 5/3; -- construct a rational number, see 7.1
 Ada.Text_IO.Put("The answer is: ");
 IO.Put(R);
 Ada.Text_IO.New_Line;
end Main;
33

```

```

34 with Rational_Numbers.IO;
 package Rational_IO renames Rational_Numbers.IO;
 -- a library unit renaming declaration

```

35 Each of the above library\_items can be submitted to the compiler separately.

35.a **Discussion:** Example of a generic package with children:

```

35.b generic
 type Element is private;
 with function Image(E : Element) return String;
 package Generic_Bags is
 type Bag is limited private; -- A bag of Elements.
 procedure Add(B : in out Bag; E : Element);
 function Bag_Image(B : Bag) return String;
 private
 type Bag is ...;
 end Generic_Bags;

```

```

35.c generic
 package Generic_Bags.Generic_Iterators is
 ... -- various additional operations on Bags.

```

```

35.d generic
 with procedure Use_Element(E : in Element);
 -- Called once per bag element.
 procedure Iterate(B : in Bag);
 end Generic_Bags.Generic_Iterators;

```

35.e A package that instantiates the above generic units:

```

35.f with Generic_Bags;
 with Generic_Bags.Generic_Iterators;
 package My_Abstraction is
 type My_Type is ...;
 function Image(X : My_Type) return String;
 package Bags_Of_My_Type is new Generic_Bags(My_Type, Image);
 package Iterators_Of_Bags_Of_My_Type is new Bags_Of_My_Type.Generic_Iterators;
 end My_Abstraction;

```

35.g In the above example, Bags\_Of\_My\_Type has a nested generic unit called Generic\_Iterators. The second with\_clause makes that nested unit visible.

35.h Here we show how the generic body could depend on one of its own children:

```

35.i with Generic_Bags.Generic_Iterators;
 package body Generic_Bags is
 procedure Add(B : in out Bag; E : Element) is ... end Add;
35.j package Iters is new Generic_Iterators;
35.k function Bag_Image(B : Bag) return String is
 Buffer : String(1..10_000);
 Last : Integer := 0;
35.l procedure Append_Image(E : in Element) is
 Im : constant String := Image(E);
 begin
 if Last /= 0 then -- Insert a comma.
 Last := Last + 1;
 Buffer(Last) := ',';
 end if;
 Buffer(Last+1 .. Last+Im'Length) := Im;
 Last := Last + Im'Length;
 end Append_Image;
35.m procedure Append_All is new Iters.Iterate(Append_Image);
 begin
 Append_All(B);
 return Buffer(1..Last);
 end Bag_Image;
 end Generic_Bags;

```

#### Extensions to Ada 83

35.n The syntax rule for library\_item is modified to allow the reserved word **private** before a library\_unit\_declaration.

35.o Children (other than children of Standard) are new in Ada 95.

35.p Library unit renaming is new in Ada 95.

*Wording Changes from Ada 83*

Standard is considered a library unit in Ada 95. This simplifies the descriptions, since it implies that the parent of each library unit is a library unit. (Standard itself has no parent, of course.) As in Ada 83, the language does not define any way to recompile Standard, since the name given in the declaration of a library unit is always interpreted in relation to Standard. That is, an attempt to compile a package Standard would result in Standard.Standard. 35.q

*Extensions to Ada 95*

{AI95-00217-06} The concept of a limited view is new. Combined with `limited_with_clauses` (see 10.1.2), they facilitate construction of mutually recursive types in multiple packages. 35.r/2

*Wording Changes from Ada 95*

{AI95-00331-01} Clarified the wording so that a grandchild generic unit will work as expected. 35.s/2

*Wording Changes from Ada 2005*

{AI05-0108-1} {AI05-0129-1} **Correction:** Clarified the wording so that it is clear that limited views of types never have discriminants and never are of incomplete types. 35.t/3

## 10.1.2 Context Clauses - With Clauses

[A `context_clause` is used to specify the `library_items` whose names are needed within a compilation unit.] 1

*Language Design Principles*

The reader should be able to understand a `context_clause` without looking ahead. Similarly, when compiling a `context_clause`, the compiler should not have to look ahead at subsequent `context_items`, nor at the compilation unit to which the `context_clause` is attached. (We have not completely achieved this.) 1.a

{AI95-00217-06} A *ripple effect* occurs when the legality of a compilation unit could be affected by adding or removing an otherwise unneeded `with_clause` on some compilation unit on which the unit depends, directly or indirectly. We try to avoid ripple effects because they make understanding and maintenance more difficult. However, ripple effects can occur because of direct visibility (as in child units); this seems impossible to eliminate. The ripple effect for `with_clauses` is somewhat similar to the Beaujolais effect (see 8.4) for `use_clauses`, which we also try to avoid. 1.b/2

*Syntax*

`context_clause ::= {context_item}` 2

`context_item ::= with_clause | use_clause` 3

{AI95-00217-06} {AI95-00262-01} `with_clause ::= limited_with_clause | nonlimited_with_clause` 4/2

`limited_with_clause ::= limited [private] with library_unit_name {, library_unit_name};` 4.1/2

`nonlimited_with_clause ::= [private] with library_unit_name {, library_unit_name};` 4.2/2

**Discussion:** {AI95-00217-06} A `limited_with_clause` makes a limited view of a unit visible. 4.a/2

{AI95-00262-01} A `with_clause` containing the reserved word **private** is called a *private with clause*. It can be thought of as making items visible only in the private part, although it really makes items visible everywhere except the visible part. It can be used both for documentation purposes (to say that a unit is not used in the visible part), and to allow access to private units that otherwise would be prohibited. 4.b/2

*Name Resolution Rules*

The *scope* of a `with_clause` that appears on a `library_unit_declaration` or `library_unit_renaming_declaration` consists of the entire declarative region of the declaration[, which includes all children and subunits]. The scope of a `with_clause` that appears on a body consists of the body[, which includes all subunits]. 5

**Discussion:** {AI95-00262-01} Suppose a nonprivate `with_clause` of a public library unit mentions one of its private siblings. (This is only allowed on the body of the public library unit.) We considered making the scope of that `with_clause` not include the visible part of the public library unit. (This would only matter for a `subprogram_body`, 5.a/2

since those are the only kinds of body that have a visible part, and only if the `subprogram_body` completes a `subprogram_declaration`, since otherwise the `with_clause` would be illegal.) We did not put in such a rule for two reasons: (1) It would complicate the wording of the rules, because we would have to split each `with_clause` into pieces, in order to correctly handle “`with P, Q;`” where P is public and Q is private. (2) The conformance rules prevent any problems. It doesn't matter if a type name in the spec of the body denotes the completion of a `private_type_declaration`.

- 5.b A `with_clause` also affects visibility within subsequent `use_clauses` and `pragmas` of the same `context_clause`, even though those are not in the scope of the `with_clause`.
- 6/2 *{AI95-00217-06}* A `library_item` (and the corresponding library unit) is *named* in a `with_clause` if it is denoted by a `library_unit_name` in the `with_clause`. A `library_item` (and the corresponding library unit) is *mentioned* in a `with_clause` if it is named in the `with_clause` or if it is denoted by a `prefix` in the `with_clause`.
- 6.a/3 **Discussion:** *{AI05-0299-1}* `With_clauses` control the visibility of declarations or renamings of library units. Mentioning a root library unit in a `with_clause` makes its declaration directly visible. Mentioning a nonroot library unit makes its declaration visible. See Clause 8 for details.
- 6.b/2 *{AI95-00114-01}* Note that this rule implies that “`with A.B.C;`” is almost equivalent to “`with A, A.B, A.B.C;`”. The reason for making a `with_clause` apply to all the ancestor units is to avoid “visibility holes” — situations in which an inner program unit is visible while an outer one is not. Visibility holes would cause semantic complexity and implementation difficulty. (This is not exactly equivalent because the latter `with_clause` names A and A.B, while the previous one does not. Whether a unit is “named” does not have any effect on visibility, however, so it is equivalent for visibility purposes.)
- 7 [Outside its own declarative region, the declaration or renaming of a library unit can be visible only within the scope of a `with_clause` that mentions it. The visibility of the declaration or renaming of a library unit otherwise follows from its placement in the environment.]

#### Legality Rules

- 8/2 *{AI95-00262-01}* If a `with_clause` of a given `compilation_unit` mentions a private child of some library unit, then the given `compilation_unit` shall be one of:
- 9/2 • *{AI95-00262-01}* the declaration, body, or subunit of a private descendant of that library unit;
  - 10/2 • *{AI95-00220-01}* *{AI95-00262-01}* the body or subunit of a public descendant of that library unit, but not a subprogram body acting as a subprogram declaration (see 10.1.4); or
  - 11/2 • *{AI95-00262-01}* the declaration of a public descendant of that library unit, in which case the `with_clause` shall include the reserved word **private**.
- 11.a/2 **Reason:** *{AI95-00262-01}* The purpose of this rule is to prevent a private child from being visible from outside the subsystem rooted at its parent. A private child can be semantically depended-on without violating this principle if it is used in a private `with_clause`.
- 11.b **Discussion:** This rule violates the one-pass `context_clauses` Language Design Principle. We rationalize this by saying that at least that Language Design Principle works for legal compilation units.
- 11.c Example:
- 11.d 

```
package A is
end A;
```
- 11.e 

```
package A.B is
end A.B;
```
- 11.f 

```
private package A.B.C is
end A.B.C;
```
- 11.g 

```
package A.B.C.D is
end A.B.C.D;
```
- 11.h 

```
with A.B.C; -- (1)
private package A.B.X is
end A.B.X;
```
- 11.i 

```
package A.B.Y is
end A.B.Y;
```

```

with A.B.C; -- (2)
package body A.B.Y is
end A.B.Y;

private with A.B.C; -- (3)
package A.B.Z is
end A.B.Z;

```

{AI95-00262-01} (1) is OK because it's a private child of A.B — it would be illegal if we made A.B.X a public child of A.B. (2) is OK because it's the body of a child of A.B. (3) is OK because it's a child of A.B, and it is a private `with_clause`. It would be illegal to say “`with A.B.C;`” on any `library_item` whose name does not start with “A.B”. Note that mentioning A.B.C.D in a `with_clause` automatically mentions A.B.C as well, so “`with A.B.C.D;`” is illegal in the same places as “`with A.B.C;`”.

{AI05-0005-1} {AI95-00262-01} {AI95-00262-01} {AI05-0077-1} {AI05-0122-1} A name denoting a `library_item` (or the corresponding declaration for a child of a generic within an instance — see 10.1.1), if it is visible only due to being mentioned in one or more `with_clauses` that include the reserved word **private**, shall appear only within:

- a private part; 13/2
- a body, but not within the `subprogram_specification` of a library subprogram body; 14/2
- a private descendant of the unit on which one of these `with_clauses` appear; or 15/2
- a pragma within a context clause. 16/2

**Ramification:** These rules apply only if all of the `with_clauses` that mention the name include the reserved word **private**. They do not apply if the name is mentioned in any `with_clause` that does not include **private**. 16.a/2

**Reason:** {AI05-0077-1} These rules make the `library_item` visible anywhere that is not visible outside the subsystem rooted at the `compilation_unit` having the private `with_clause`, including private parts of packages nested in the visible part, private parts of child packages, the visible part of private children, and context clause pragmas like `Elaborate_All`. 16.b/3

We considered having the scope of a private `with_clause` not include the visible part. However, that rule would mean that moving a declaration between the visible part and the private part could change its meaning from one legal interpretation to a different legal interpretation. For example: 16.c/2

```

package A is
 function B return Integer;
end A;

function B return Integer;

with A;
private with B;
package C is
 use A;
 V1 : Integer := B; -- (1)
private
 V2 : Integer := B; -- (2)
end C;

```

If we say that library subprogram B is not in scope in the visible part of C, then the B at (1) resolves to A.B, while (2) resolves to library unit B. Simply moving a declaration could silently change its meaning. With the legality rule defined above, the B at (1) is illegal. If the user really meant A.B, they still can say that. 16.g/2

{AI95-00217-06} [A `library_item` mentioned in a `limited_with_clause` shall be the implicit declaration of the limited view of a library package, not the declaration of a subprogram, generic unit, generic instance, or a renaming.] 17/2

**Proof:** This is redundant because only such implicit declarations are visible in a `limited_with_clause`. See 10.1.6. 17.a/2

{AI95-00217-06} {AI95-00412-01} A `limited_with_clause` shall not appear on a `library_unit_body`, `subunit`, or `library_unit_renaming_declaration`. 18/2

**Reason:** {AI95-00412-01} We don't allow a `limited_with_clause` on a `library_unit_renaming_declaration` because it would be useless and therefore probably is a mistake. A renaming cannot appear in a `limited_with_clause` (by the rule prior to this one), and a renaming of a limited view cannot appear in a `nonlimited_with_clause` (because the name would not be within the scope of a `with_clause` denoting the package, see 8.5.3). Nor could it be the parent of another unit. That doesn't leave anywhere that the name of such a renaming **could** appear, so we simply make writing it illegal. 18.a/2

- 19/2 {AI95-00217-06} A `limited_with_clause` that names a library package shall not appear:
- 20/3 • {AI95-00217-06} {AI05-0040-1} in the `context_clause` for the explicit declaration of the named library package or any of its descendants;
- 20.a/2 **Reason:** We have to explicitly disallow
- 20.b/2 

```
limited with P;
package P is ...
```
- 20.c/2 as we can't depend on the semantic dependence rules to do it for us as with regular withs. This says “named” and not “mentioned” in order that
- 20.d/2 

```
limited private with P.Child;
package P is ...
```
- 20.e/2 can be used to allow a mutual dependence between the private part of P and the private child P.Child, which occurs in interfacing and other problems. Since the child always semantically depends on the parent, this is the only way such a dependence can be broken.
- 20.f/3 {AI05-0040-1} The part about descendants catches examples like
- 20.g/3 

```
limited with P;
package P.Child is ...
```
- 21/3 • {AI95-00217-06} {AI05-0077-1} {AI05-0262-1} within a `context_clause` for a `library_item` that is within the scope of a `nonlimited_with_clause` that mentions the same library package; or
- 21.a.1/3 **Ramification:** {AI05-0077-1} This applies to `nonlimited_with_clauses` found in the same `context_clause`, as well as `nonlimited_with_clauses` found on parent units.
- 21.a/3 **Reason:** {AI05-0077-1} Such a `limited_with_clause` could have no effect, and would be confusing. If a `nonlimited_with_clause` for the same package is inherited from a parent unit or given in the `context_clause`, the full view is available, which strictly provides more information than the limited view.
- 22/3 • {AI95-00217-06} {AI05-0077-1} {AI05-0262-1} within a `context_clause` for a `library_item` that is within the scope of a `use_clause` that names an entity declared within the declarative region of the library package.
- 22.a.1/3 **Ramification:** {AI05-0077-1} This applies to `use_clauses` found in the same `context_clause`, as well as `use_clauses` found in (or on) parent units.
- 22.a/2 **Reason:** This prevents visibility issues, where whether an entity is an incomplete or full view depends on how the name of the entity is written. The `limited_with_clause` cannot be useful, as we must have the full view available in the parent in order for the `use_clause` to be legal.

## NOTES

- 23/2 3 {AI95-00217-06} A `library_item` mentioned in a `nonlimited_with_clause` of a compilation unit is visible within the compilation unit and hence acts just like an ordinary declaration. Thus, within a compilation unit that mentions its declaration, the name of a library package can be given in `use_clauses` and can be used to form expanded names, a library subprogram can be called, and instances of a generic library unit can be declared. If a child of a parent generic package is mentioned in a `nonlimited_with_clause`, then the corresponding declaration nested within each visible instance is visible within the compilation unit. Similarly, a `library_item` mentioned in a `limited_with_clause` of a compilation unit is visible within the compilation unit and thus can be used to form expanded names.
- 23.a **Ramification:** The rules given for `with_clauses` are such that the same effect is obtained whether the name of a library unit is mentioned once or more than once by the applicable `with_clauses`, or even within a given `with_clause`.
- 23.b If a `with_clause` mentions a `library_unit_renaming_declaration`, it only “mentions” the prefixes appearing explicitly in the `with_clause` (and the renamed view itself); the `with_clause` is not defined to mention the ancestors of the renamed entity. Thus, if X renames Y.Z, then “with X;” does not make the declarations of Y or Z visible. Note that this does not cause the dreaded visibility holes mentioned above.

*Examples*

- 24/2 {AI95-00433-01} 

```
package Office is
end Office;
```
- 25/2 {AI95-00433-01} 

```
with Ada.Strings.Unbounded;
package Office.Locations is
 type Location is new Ada.Strings.Unbounded.Unbounded_String;
end Office.Locations;
```

```

{AI95-00433-01} limited with Office.Departments; -- types are incomplete 26/2
private with Office.Locations; -- only visible in private part
package Office.Employees is
 type Employee is private;

 function Dept_Of(Emp : Employee) return access Departments.Department; 27/2
 procedure Assign_Dept(Emp : in out Employee;
 Dept : access Departments.Department);

 ...
private
 type Employee is
 record
 Dept : access Departments.Department;
 Loc : Locations.Location;
 ...
 end record;
end Office.Employees;

limited with Office.Employees;
package Office.Departments is
 type Department is private;

 function Manager_Of(Dept : Department) return access Employees.Employee; 30/2
 procedure Assign_Manager(Dept : in out Department;
 Mgr : access Employees.Employee);

 ...
end Office.Departments;

```

{AI95-00433-01} The `limited_with_clause` may be used to support mutually dependent abstractions that are split across multiple packages. In this case, an employee is assigned to a department, and a department has a manager who is an employee. If a `with_clause` with the reserved word **private** appears on one library unit and mentions a second library unit, it provides visibility to the second library unit, but restricts that visibility to the private part and body of the first unit. The compiler checks that no use is made of the second unit in the visible part of the first unit. 31/2

#### Extensions to Ada 83

- The syntax rule for `with_clause` is modified to allow expanded name notation. 31.a
- A `use_clause` in a `context_clause` may be for a package (or type) nested in a library package. 31.b

#### Wording Changes from Ada 83

- The syntax rule for `context_clause` is modified to more closely reflect the semantics. The Ada 83 syntax rule implies that the `use_clauses` that appear immediately after a particular `with_clause` are somehow attached to that `with_clause`, which is not true. The new syntax allows a `use_clause` to appear first, but that is prevented by a textual rule that already exists in Ada 83. 31.c
- The concept of “scope of a `with_clause`” (which is a region of text) replaces RM83’s notion of “apply to” (a `with_clause` applies to a `library_item`) The visibility rules are interested in a region of text, not in a set of compilation units. 31.d
- No need to define “apply to” for `use_clauses`. Their semantics are fully covered by the “scope (of a `use_clause`)” definition in 8.4. 31.e

#### Incompatibilities With Ada 95

- {AI95-00220-01} **Amendment Correction:** A subprogram body acting as a declaration cannot **with** a private child unit. This would allow public export of types declared in private child packages, and thus cannot be allowed. This was allowed by mistake in Ada 95; a subprogram that does this will now be illegal. 31.f/2

#### Extensions to Ada 95

- {AI95-00217-06} `limited_with_clauses` are new. They make a limited view of a package visible, where all of the types in the package are incomplete. They facilitate construction of mutually recursive types in multiple packages. 31.g/2
- {AI95-00262-01} {AI05-0077-1} The syntax rules for `with_clause` are modified to allow the reserved word **private**. Private `with_clauses` do not allow the use of their `library_item` in the visible part of their `compilation_unit`. They also allow using private units in more locations than in Ada 95. 31.h/3

*Incompatibilities With Ada 2005*

- 31.i/3 {AI05-0040-1} **Correction:** Added missing rule that a limited with clause cannot name an ancestor unit. This is incompatible if an Ada 2005 program does this, but as this is a new Ada 2005 feature and the unintentionally allowed capability is not useful, the incompatibility is very unlikely to occur in practice.

*Wording Changes from Ada 2005*

- 31.j/3 {AI05-0077-1} **Correction:** Fixed wording so that we are not checking whether something in a `context_clause` is “within the scope of” something, as `context_clauses` are never included in anything's scope. The intended meaning is unchanged, however.
- 31.k/3 {AI05-0122-1} **Correction:** Fixed wording so the rules for private with clauses also apply to "sprouted" generic child units.

**10.1.3 Subunits of Compilation Units**

- 1 [Subunits are like child units, with these (important) differences: subunits support the separate compilation of bodies only (not declarations); the parent contains a `body_stub` to indicate the existence and place of each of its subunits; declarations appearing in the parent's body can be visible within the subunits.]

*Syntax*

- 2 `body_stub ::=`  
`subprogram_body_stub | package_body_stub | task_body_stub | protected_body_stub`

- 3/3 {AI95-00218-03} {AI05-0267-1} `subprogram_body_stub ::=`  
`[overriding_indicator]`  
`subprogram_specification is separate`  
`[aspect_specification];`

- 3.a **Discussion:** Although this syntax allows a `parent_unit_name`, that is disallowed by 10.1.1, “Compilation Units - Library Units”.

- 4 `package_body_stub ::=`  
`package body defining_identifier is separate`  
`[aspect_specification];`

- 5 `task_body_stub ::=`  
`task body defining_identifier is separate`  
`[aspect_specification];`

- 6 `protected_body_stub ::=`  
`protected body defining_identifier is separate`  
`[aspect_specification];`

- 7 `subunit ::= separate (parent_unit_name) proper_body`

*Legality Rules*

- 8/2 {AI95-00243-01} The *parent body* of a subunit is the body of the program unit denoted by its `parent_unit_name`. The term *subunit* is used to refer to a subunit and also to the `proper_body` of a subunit. The *subunits of a program unit* include any subunit that names that program unit as its parent, as well as any subunit that names such a subunit as its parent (recursively).

- 8.a.1/2 **Reason:** {AI95-00243-01} We want any rule that applies to a subunit to apply to a subunit of a subunit as well.

- 9 The parent body of a subunit shall be present in the current environment, and shall contain a corresponding `body_stub` with the same `defining_identifier` as the subunit.

- 9.a **Discussion:** This can't be a Name Resolution Rule, because a subunit is not a complete context.

{AI05-0004-1} A `package_body_stub` shall be the completion of a `package_declaration` or `generic_package_declaration`; a `task_body_stub` shall be the completion of a `task_declaration`; a `protected_body_stub` shall be the completion of a `protected_declaration`. 10/3

In contrast, a `subprogram_body_stub` need not be the completion of a previous declaration, [in which case the `_stub` declares the subprogram]. If the `_stub` is a completion, it shall be the completion of a `subprogram_declaration` or `generic_subprogram_declaration`. The profile of a `subprogram_body_stub` that completes a declaration shall conform fully to that of the declaration. 11

**Discussion:** The part about `subprogram_body_stubs` echoes the corresponding rule for `subprogram_bodies` in 6.3, “Subprogram Bodies”. 11.a

A subunit that corresponds to a `body_stub` shall be of the same kind (`package_`, `subprogram_`, `task_`, or `protected_`) as the `body_stub`. The profile of a `subprogram_body` subunit shall be fully conformant to that of the corresponding `body_stub`. 12

A `body_stub` shall appear immediately within the `declarative_part` of a compilation unit body. This rule does not apply within an instance of a generic unit. 13

**Discussion:** This is a methodological restriction; that is, it is not necessary for the semantics of the language to make sense. 13.a

The `defining_identifiers` of all `body_stubs` that appear immediately within a particular `declarative_part` shall be distinct. 14

#### *Post-Compilation Rules*

For each `body_stub`, there shall be a subunit containing the corresponding `proper_body`. 15

#### NOTES

4 The rules in 10.1.4, “The Compilation Process” say that a `body_stub` is equivalent to the corresponding `proper_body`. This implies: 16

- Visibility within a subunit is the visibility that would be obtained at the place of the corresponding `body_stub` (within the parent body) if the `context_clause` of the subunit were appended to that of the parent body. 17

**Ramification:** Recursively. Note that this transformation might make the parent illegal; hence it is not a true equivalence, but applies only to visibility within the subunit. 17.a

- The effect of the elaboration of a `body_stub` is to elaborate the subunit. 18

**Ramification:** The elaboration of a subunit is part of its parent body's elaboration, whereas the elaboration of a child unit is not part of its parent declaration's elaboration. 18.a

**Ramification:** A `library_item` that is mentioned in a `with_clause` of a subunit can be hidden (from direct visibility) by a declaration (with the same `identifier`) given in the subunit. Moreover, such a `library_item` can even be hidden by a declaration given within the parent body since a library unit is declared in its parent's declarative region; this however does not affect the interpretation of the `with_clauses` themselves, since only `library_items` are visible or directly visible in `with_clauses`. 18.b

The body of a protected operation cannot be a subunit. This follows from the syntax rules. The body of a protected unit can be a subunit. 18.c

#### *Examples*

The package `Parent` is first written without subunits: 19

```
package Parent is
 procedure Inner;
end Parent;
```

20

```

21 with Ada.Text_IO;
 package body Parent is
 Variable : String := "Hello, there.";
 procedure Inner is
 begin
 Ada.Text_IO.Put_Line(Variable);
 end Inner;
 end Parent;

```

22 The body of procedure Inner may be turned into a subunit by rewriting the package body as follows (with the declaration of Parent remaining the same):

```

23 package body Parent is
 Variable : String := "Hello, there.";
 procedure Inner is separate;
 end Parent;

24 with Ada.Text_IO;
 separate (Parent)
 procedure Inner is
 begin
 Ada.Text_IO.Put_Line(Variable);
 end Inner;

```

*Extensions to Ada 83*

24.a Subunits of the same ancestor library unit are no longer restricted to have distinct identifiers. Instead, we require only that the full expanded names be distinct.

*Extensions to Ada 95*

24.b/2 {AI95-00218-03} An overriding\_indicator (see 8.3.1) is allowed on a subprogram stub.

*Wording Changes from Ada 95*

24.c/2 {AI95-00243-01} Clarified that a subunit of a subunit is still a subunit.

*Extensions to Ada 2005*

24.d/3 {AI05-0267-1} An optional aspect\_specification can be used in a body\_stub. This is described in 13.1.1.

## 10.1.4 The Compilation Process

1 Each compilation unit submitted to the compiler is compiled in the context of an *environment declarative\_part* (or simply, an *environment*), which is a conceptual *declarative\_part* that forms the outermost declarative region of the context of any compilation. At run time, an environment forms the *declarative\_part* of the body of the environment task of a partition (see 10.2, “Program Execution”).

1.a **Ramification:** At compile time, there is no particular construct that the declarative region is considered to be nested within — the environment is the universe.

1.b **To be honest:** The environment is really just a portion of a *declarative\_part*, since there might, for example, be bodies that do not yet exist.

2 The *declarative\_items* of the environment are *library\_items* appearing in an order such that there are no forward semantic dependences. Each included subunit occurs in place of the corresponding stub. The visibility rules apply as if the environment were the outermost declarative region, except that *with\_clauses* are needed to make declarations of library units visible (see 10.1.2).

3/2 {AI95-00217-06} The mechanisms for creating an environment and for adding and replacing compilation units within an environment are implementation defined. The mechanisms for adding a compilation unit mentioned in a *limited\_with\_clause* to an environment are implementation defined.

3.a **Implementation defined:** The mechanisms for creating an environment and for adding and replacing compilation units.

**Implementation defined:** The mechanisms for adding a compilation unit mentioned in a `limited_with_clause` to an environment. 3.a.1/2

**Ramification:** The traditional model, used by most Ada 83 implementations, is that one places a compilation unit in the environment by compiling it. Other models are possible. For example, an implementation might define the environment to be a directory; that is, the compilation units in the environment are all the compilation units in the source files contained in the directory. In this model, the mechanism for replacing a compilation unit with a new one is simply to edit the source file containing that compilation unit. 3.b

#### *Name Resolution Rules*

{8652/0032} {AI95-00192-01} {AI05-0264-1} If a `library_unit_body` that is a `subprogram_body` is submitted to the compiler, it is interpreted only as a completion if a `library_unit_declaration` with the same `defining_program_unit_name` already exists in the environment for a subprogram other than an instance of a generic subprogram or for a generic subprogram (even if the profile of the body is not type conformant with that of the declaration); otherwise, the `subprogram_body` is interpreted as both the declaration and body of a library subprogram. 4/3

**Ramification:** The principle here is that a `subprogram_body` should be interpreted as only a completion if and only if it “might” be legal as the completion of some preexisting declaration, where “might” is defined in a way that does not require overload resolution to determine. 4.a

Hence, if the preexisting declaration is a `subprogram_declaration` or `generic_subprogram_declaration`, we treat the new `subprogram_body` as its completion, because it “might” be legal. If it turns out that the profiles don't fully conform, it's an error. In all other cases (the preexisting declaration is a package or a generic package, or an instance of a generic subprogram, or a renaming, or a “spec-less” subprogram, or in the case where there is no preexisting thing), the `subprogram_body` declares a new subprogram. 4.b

See also AI83-00266/09. 4.c

#### *Legality Rules*

When a compilation unit is compiled, all compilation units upon which it depends semantically shall already exist in the environment; the set of these compilation units shall be *consistent* in the sense that the new compilation unit shall not semantically depend (directly or indirectly) on two different versions of the same compilation unit, nor on an earlier version of itself. 5

**Discussion:** For example, if package declarations A and B both say “`with X;`”, and the user compiles a compilation unit that says “`with A, B;`”, then the A and B have to be talking about the same version of X. 5.a

**Ramification:** What it means to be a “different version” is not specified by the language. In some implementations, it means that the compilation unit has been recompiled. In others, it means that the source of the compilation unit has been edited in some significant way. 5.b

Note that an implementation cannot require the existence of compilation units upon which the given one does not semantically depend. For example, an implementation is required to be able to compile a compilation unit that says “`with A;`” when A's body does not exist. It has to be able to detect errors without looking at A's body. 5.c

{AI05-0229-1} Similarly, the implementation has to be able to compile a call to a subprogram for which aspect `Inline` has been specified without seeing the body of that subprogram — inlining would not be achieved in this case, but the call is still legal. 5.d/3

{AI95-00217-06} {AI05-0005-1} The consistency rule applies to limited views as well as the full view of a compilation unit. That means that an implementation needs a way to enforce consistency of limited views, not just of full views. 5.e/3

#### *Implementation Permissions*

{AI95-00217-06} The implementation may require that a compilation unit be legal before it can be mentioned in a `limited_with_clause` or it can be inserted into the environment. 6/2

{AI95-00214-01} {AI05-0229-1} When a compilation unit that declares or renames a library unit is added to the environment, the implementation may remove from the environment any preexisting `library_item` or `subunit` with the same full expanded name. When a compilation unit that is a subunit or the body of a library unit is added to the environment, the implementation may remove from the environment any 7/3

preexisting version of the same compilation unit. When a compilation unit that contains a `body_stub` is added to the environment, the implementation may remove any preexisting `library_item` or subunit with the same full expanded name as the `body_stub`. When a given compilation unit is removed from the environment, the implementation may also remove any compilation unit that depends semantically upon the given one. If the given compilation unit contains the body of a subprogram for which aspect `Inline` is `True`, the implementation may also remove any compilation unit containing a call to that subprogram.

- 7.a/3 **Ramification:** *{AI05-0005-1}* The permissions given in this paragraph correspond to the traditional model, where compilation units enter the environment by being compiled into it, and the compiler checks their legality at that time. An implementation model in which the environment consists of all source files in a given directory might not want to take advantage of these permissions. Compilation units would not be checked for legality as soon as they enter the environment; legality checking would happen later, when compilation units are compiled. In this model, compilation units might never be automatically removed from the environment; they would be removed when the user explicitly deletes a source file.
- 7.b Note that the rule is recursive: if the above permission is used to remove a compilation unit containing an inlined subprogram call, then compilation units that depend semantically upon the removed one may also be removed, and so on.
- 7.c Note that here we are talking about dependences among existing compilation units in the environment; it doesn't matter what `with_clauses` are attached to the new compilation unit that triggered all this.
- 7.d/3 *{AI05-0229-1}* An implementation may have other modes in which compilation units in addition to the ones mentioned above are removed. For example, an implementation might inline subprogram calls without an explicit aspect `Inline`. If so, it either has to have a mode in which that optimization is turned off, or it has to automatically regenerate code for the inlined calls without requiring the user to resubmit them to the compiler.
- 7.d.1/2 **Discussion:** *{8652/0108}* *{AI95-00077-01}* *{AI95-00114-01}* In the standard mode, implementations may only remove units from the environment for one of the reasons listed here, or in response to an explicit user command to modify the environment. It is not intended that the act of compiling a unit is one of the “mechanisms” for removing units other than those specified by this International Standard.
- 7.e/2 *{AI95-00214-01}* These rules are intended to ensure that an implementation never need keep more than one compilation unit with any full expanded name. In particular, it is not necessary to be able to have a subunit and a child unit with the same name in the environment at one time.

## NOTES

- 8 5 The rules of the language are enforced across compilation and compilation unit boundaries, just as they are enforced within a single compilation unit.
- 8.a/3 **Ramification:** *{AI05-0299-1}* Note that Clause 1 requires an implementation to detect illegal compilation units at compile time.
- 9 6 An implementation may support a concept of a *library*, which contains `library_items`. If multiple libraries are supported, the implementation has to define how a single environment is constructed when a compilation unit is submitted to the compiler. Naming conflicts between different libraries might be resolved by treating each library as the root of a hierarchy of child library units.
- 9.a **Implementation Note:** Alternatively, naming conflicts could be resolved via some sort of hiding rule.
- 9.b **Discussion:** For example, the implementation might support a command to import library Y into library X. If a root library unit called LU (that is, `Standard.LU`) exists in Y, then from the point of view of library X, it could be called `Y.LU`. X might contain library units that say, “**with** `Y.LU`;”.
- 10 7 A compilation unit containing an instantiation of a separately compiled generic unit does not semantically depend on the body of the generic unit. Therefore, replacing the generic body in the environment does not result in the removal of the compilation unit containing the instantiation.
- 10.a **Implementation Note:** Therefore, implementations have to be prepared to automatically instantiate generic bodies at link-time, as needed. This might imply a complete automatic recompilation, but it is the intent of the language that generic bodies can be (re)instantiated without forcing all of the compilation units that semantically depend on the compilation unit containing the instantiation to be recompiled.
- Extensions to Ada 83*
- 10.b/2 *{AI95-00077-01}* *{AI95-00114-01}* Ada 83 allowed implementations to require that the body of a generic unit be available when the instantiation is compiled; that permission is dropped in Ada 95. This isn't really an extension (it doesn't allow Ada users to write anything that they couldn't in Ada 83), but there isn't a more appropriate category, and it does allow users more flexibility when developing programs.

*Wording Changes from Ada 95*

{8652/0032} {AI95-00192-01} **Corrigendum:** The wording was clarified to ensure that a `subprogram_body` is not considered a completion of an instance of a generic subprogram. 10.c/2

{AI95-00214-01} The permissions to remove a unit from the environment were clarified to ensure that it is never necessary to keep multiple (sub)units with the same full expanded name in the environment. 10.d/2

{AI95-00217-06} Units mentioned in a `limited_with_clause` were added to several rules; limited views have the same presence in the environment as the corresponding full views. 10.e/2

**10.1.5 Pragmas and Program Units**

[This subclause discusses pragmas related to program units, library units, and compilations.] 1

*Name Resolution Rules*

Certain pragmas are defined to be *program unit pragmas*. A name given as the argument of a program unit pragma shall resolve to denote the declarations or renamings of one or more program units that occur immediately within the declarative region or compilation in which the pragma immediately occurs, or it shall resolve to denote the declaration of the immediately enclosing program unit (if any); the pragma applies to the denoted program unit(s). If there are no names given as arguments, the pragma applies to the immediately enclosing program unit. 2

**Ramification:** The fact that this is a Name Resolution Rule means that the pragma will not apply to declarations from outer declarative regions. 2.a

*Legality Rules*

A program unit pragma shall appear in one of these places: 3

- At the place of a `compilation_unit`, in which case the pragma shall immediately follow in the same compilation (except for other pragmas) a `library_unit_declaration` that is a `subprogram_declaration`, `generic_subprogram_declaration`, or `generic_instantiation`, and the pragma shall have an argument that is a name denoting that declaration. 4

**Ramification:** The name has to denote the immediately preceding `library_unit_declaration`. 4.a

- {8652/0033} {AI95-00136-01} Immediately within the visible part of a program unit and before any nested declaration (but not within a generic formal part), in which case the argument, if any, shall be a `direct_name` that denotes the immediately enclosing program unit declaration. 5/1

**Ramification:** The argument is optional in this case. 5.a

- At the place of a declaration other than the first, of a `declarative_part` or program unit declaration, in which case the pragma shall have an argument, which shall be a `direct_name` that denotes one or more of the following (and nothing else): a `subprogram_declaration`, a `generic_subprogram_declaration`, or a `generic_instantiation`, of the same `declarative_part` or program unit declaration. 6

**Ramification:** If you want to denote a `subprogram_body` that is not a completion, or a `package_declaration`, for example, you have to put the pragma inside. 6.a

{AI05-0132-1} Certain program unit pragmas are defined to be *library unit pragmas*. If a library unit pragma applies to a program unit, the program unit shall be a library unit. 7/3

**Ramification:** This, together with the rules for program unit pragmas above, implies that if a library unit pragma applies to a `subprogram_declaration` (and similar things), it has to appear immediately after the `compilation_unit`, whereas if the pragma applies to a `package_declaration`, a `subprogram_body` that is not a completion (and similar things), it has to appear inside, as the first `declarative_item`. 7.a

*Static Semantics*

{8652/0034} {AI95-00041-01} A library unit pragma that applies to a generic unit does not apply to its instances, unless a specific rule for the pragma specifies the contrary. 7.1/1

*Post-Compilation Rules*

- 8 Certain pragmas are defined to be *configuration pragmas*; they shall appear before the first `compilation_unit` of a compilation. [They are generally used to select a partition-wide or system-wide option.] The pragma applies to all `compilation_units` appearing in the compilation, unless there are none, in which case it applies to all future `compilation_units` compiled into the same environment.

*Implementation Permissions*

- 9/2 *{AI95-00212-01}* An implementation may require that configuration pragmas that select partition-wide or system-wide options be compiled when the environment contains no `library_items` other than those of the predefined environment. In this case, the implementation shall still accept configuration pragmas in individual compilations that confirm the initially selected partition-wide or system-wide options.

*Implementation Advice*

- 10/1 *{8652/0034}* *{AI95-00041-01}* When applied to a generic unit, a program unit pragma that is not a library unit pragma should apply to each instance of the generic unit for which there is not an overriding pragma applied directly to the instance.
- 10.a/2 **Implementation Advice:** When applied to a generic unit, a program unit pragma that is not a library unit pragma should apply to each instance of the generic unit for which there is not an overriding pragma applied directly to the instance.

*Wording Changes from Ada 95*

- 10.b/2 *{8652/0033}* *{AI95-00136-01}* **Corrigendum:** The wording was corrected to ensure that a program unit pragma cannot appear in private parts or generic formal parts.
- 10.c/2 *{8652/0034}* *{AI95-00041-01}* **Corrigendum:** The wording was clarified to explain the meaning of program unit and library unit pragmas in generic units.
- 10.d/2 The Implementation Advice added by the Corrigendum was moved, as it was not in the normal order. (This changes the paragraph number.) It originally was directly after the new Static Semantics rule.
- 10.e/2 *{AI95-00212-01}* The permission to place restrictions was clarified to:
- 10.f/2
- Ensure that it applies only to partition-wide configuration pragmas, not ones like `Assertion_Policy` (see 11.4.2), which can be different in different units; and
- 10.g/2
- Ensure that confirming pragmas are always allowed.

*Wording Changes from Ada 2005*

- 10.h/3 *{AI05-0132-1}* **Correction:** A library unit pragma must apply directly to a library unit, even if no name is given in the pragma.

## 10.1.6 Environment-Level Visibility Rules

- 1 [The normal visibility rules do not apply within a `parent_unit_name` or a `context_clause`, nor within a pragma that appears at the place of a compilation unit. The special visibility rules for those contexts are given here.]

*Static Semantics*

- 2/2 *{AI95-00217-06}* *{AI95-00312-01}* Within the `parent_unit_name` at the beginning of an explicit `library_item`, and within a `nonlimited_with_clause`, the only declarations that are visible are those that are explicit `library_items` of the environment, and the only declarations that are directly visible are those that are explicit root `library_items` of the environment. Within a `limited_with_clause`, the only declarations that are visible are those that are the implicit declaration of the limited view of a library package of the environment, and the only declarations that are directly visible are those that are the implicit declaration of the limited view of a root library package.

- Ramification:** In “`package P.Q.R is ... end P.Q.R;`”, this rule requires P to be a root library unit, and Q to be a library unit (because those are the things that are directly visible and visible). Note that visibility does not apply between the “`end`” and the “`;`”.
- Physically nested declarations are not visible at these places.
- Although Standard is visible at these places, it is impossible to name it, since it is not directly visible, and it has no parent.
- {AI95-00217-06} Only compilation units defining limited views can be mentioned in a `limited_with_clause`, while only compilation units defining full views (that is, the explicit declarations) can be mentioned in a `nonlimited_with_clause`. This resolves the conflict inherent in having two compilation units with the same defining name.
- This paragraph was deleted. {AI95-00312-01}*
- Within a `use_clause` or `pragma` that is within a `context_clause`, each `library_item` mentioned in a previous `with_clause` of the same `context_clause` is visible, and each root `library_item` so mentioned is directly visible. In addition, within such a `use_clause`, if a given declaration is visible or directly visible, each declaration that occurs immediately within the given declaration's visible part is also visible. No other declarations are visible or directly visible.
- Discussion:** Note the word “same”. For example, if a `with_clause` on a declaration mentions X, this does not make X visible in `use_clauses` and `pragmas` that are on the body. The reason for this rule is the one-pass `context_clauses` Language Design Principle.
- Note that the second part of the rule does not mention `pragmas`.
- Within the `parent_unit_name` of a subunit, `library_items` are visible as they are in the `parent_unit_name` of a `library_item`; in addition, the declaration corresponding to each `body_stub` in the environment is also visible.
- Ramification:** For a subprogram without a separate `subprogram_declaration`, the `body_stub` itself is the declaration.
- Within a `pragma` that appears at the place of a compilation unit, the immediately preceding `library_item` and each of its ancestors is visible. The ancestor root `library_item` is directly visible.
- {AI95-00312-01} Notwithstanding the rules of 4.1.3, an expanded name in a `with_clause`, a `pragma` in a `context_clause`, or a `pragma` that appears at the place of a compilation unit may consist of a `prefix` that denotes a generic package and a `selector_name` that denotes a child of that generic package. [(The child is necessarily a generic unit; see 10.1.1.)]
- Reason:** This rule allows `with A.B;` and `pragma Elaborate(A.B);` where A is a generic library package and B is one of its (generic) children. This is necessary because it is not normally legal to use an expanded name to reach inside a generic package.
- Wording Changes from Ada 83*
- The special visibility rules that apply within a `parent_unit_name` or a `context_clause`, and within a `pragma` that appears at the place of a `compilation_unit` are clarified.
- Note that a `context_clause` is not part of any declarative region.
- We considered making the visibility rules within `parent_unit_names` and `context_clauses` follow from the context of compilation. However, this attempt failed for various reasons. For example, it would require `use_clauses` in `context_clauses` to be within the declarative region of Standard, which sounds suspiciously like a kludge. And we would still need a special rule to prevent seeing things (in our own `context_clause`) that were with-ed by our parent, etc.
- Wording Changes from Ada 95*
- {AI95-00217-06} Added separate visibility rules for `limited_with_clauses`; the existing rules apply only to `nonlimited_with_clauses`.
- {AI95-00312-01} Clarified that the name of a generic child unit may appear in a `pragma` in a `context_clause`.

## 10.2 Program Execution

1 An Ada *program* consists of a set of *partitions*[], which can execute in parallel with one another, possibly in a separate address space, and possibly on a separate computer.]

### Post-Compilation Rules

2 A partition is a program or part of a program that can be invoked from outside the Ada implementation. [For example, on many systems, a partition might be an executable file generated by the system linker.] The user can *explicitly assign* library units to a partition. The assignment is done in an implementation-defined manner. The compilation units included in a partition are those of the explicitly assigned library units, as well as other compilation units *needed by* those library units. The compilation units needed by a given compilation unit are determined as follows (unless specified otherwise via an implementation-defined *pragma*, or by some other implementation-defined means):

2.a **Discussion:** From a run-time point of view, an Ada 95 partition is identical to an Ada 83 program — implementations were always allowed to provide inter-program communication mechanisms. The additional semantics of partitions is that interfaces between them can be defined to obey normal language rules (as is done in Annex E, “Distributed Systems”), whereas interfaces between separate programs had no particular semantics.

2.b **Implementation defined:** The manner of explicitly assigning library units to a partition.

2.c **Implementation defined:** The implementation-defined means, if any, of specifying which compilation units are needed by a given compilation unit.

2.d **Discussion:** There are no pragmas that “specify otherwise” defined by the core language. However, an implementation is allowed to provide such pragmas, and in fact Annex E, “Distributed Systems” defines some pragmas whose semantics includes reducing the set of compilation units described here.

- 3 • A compilation unit needs itself;
- 4 • If a compilation unit is needed, then so are any compilation units upon which it depends semantically;
- 5 • If a `library_unit_declaration` is needed, then so is any corresponding `library_unit_body`;
- 6/2 • `{AI95-00217-06}` If a compilation unit with stubs is needed, then so are any corresponding subunits;

6.a **Discussion:** Note that in the environment, the stubs are replaced with the corresponding `proper_bodies`.

- 6.1/2 • `{AI95-00217-06}` If the (implicit) declaration of the limited view of a library package is needed, then so is the explicit declaration of the library package.

6.b **Discussion:** Note that a child unit is not included just because its parent is included — to include a child, mention it in a `with_clause`.

6.c/2 `{AI95-00217-06}` A package is included in a partition even if the only reference to it is in a `limited_with_clause`. While this isn't strictly necessary (no objects of types imported from such a unit can be created), it ensures that all incomplete types are eventually completed, and is the least surprising option.

7 The user can optionally designate (in an implementation-defined manner) one subprogram as the *main subprogram* for the partition. A main subprogram, if specified, shall be a subprogram.

7.a **Discussion:** This may seem superfluous, since it follows from the definition. But we would like to have every error message that might be generated (before run time) by an implementation correspond to some explicitly stated “shall” rule.

7.b Of course, this does not mean that the “shall” rules correspond one-to-one with an implementation's error messages. For example, the rule that says overload resolution “shall” succeed in producing a single interpretation would correspond to many error messages in a good implementation — the implementation would want to explain to the user exactly why overload resolution failed. This is especially true for the syntax rules — they are considered part of overload resolution, but in most cases, one would expect an error message based on the particular syntax rule that was violated.

7.c **Implementation defined:** The manner of designating the main subprogram of a partition.

- Ramification:** An implementation cannot require the user to specify, say, all of the library units to be included. It has to support, for example, perhaps the most typical case, where the user specifies just one library unit, the main program. The implementation has to do the work of tracking down all the other ones. 7.d
- Each partition has an anonymous *environment task*[], which is an implicit outermost task whose execution elaborates the *library\_items* of the *environment declarative\_part*, and then calls the main subprogram, if there is one. A partition's execution is that of its tasks.[] 8
- Ramification:** An environment task has no master; all nonenvironment tasks have masters. 8.a
- An implementation is allowed to support multiple concurrent executions of the same partition. 8.b
- [The order of elaboration of library units is determined primarily by the *elaboration dependences*.] There is an elaboration dependence of a given *library\_item* upon another if the given *library\_item* or any of its subunits depends semantically on the other *library\_item*. In addition, if a given *library\_item* or any of its subunits has a *pragma Elaborate* or *Elaborate\_All* that names another library unit, then there is an elaboration dependence of the given *library\_item* upon the body of the other library unit, and, for *Elaborate\_All* only, upon each *library\_item* needed by the declaration of the other library unit. 9
- Discussion:** {8652/0107} {AI95-00180-01} {AI95-00256-01} “Mentions” was used informally in the above rule; it was not intended to refer to the definition of *mentions* in 10.1.2. It was changed to “names” to make this clear. 9.a.1/2
- See above for a definition of which *library\_items* are “needed by” a given declaration. 9.a
- Note that elaboration dependences are among *library\_items*, whereas the other two forms of dependence are among compilation units. Note that elaboration dependence includes semantic dependence. It's a little bit sad that *pragma Elaborate\_Body* can't be folded into this mechanism. It follows from the definition that the elaboration dependence relationship is transitive. Note that the wording of the rule does not need to take into account a semantic dependence of a *library\_item* or one of its subunits upon a subunit of a different library unit, because that can never happen. 9.b
- The environment task for a partition has the following structure: 10
- ```
task Environment_Task; 11
task body Environment_Task is 12
    ... (1) -- The environment declarative_part
           -- (that is, the sequence of library_items) goes here.
begin
    ... (2) -- Call the main subprogram, if there is one.
end Environment_Task;
```
- Ramification:** The name of the environment task is written in italics here to indicate that this task is anonymous. 12.a
- Discussion:** The model is different for a “passive partition” (see E.1). Either there is no environment task, or its *sequence_of_statements* is an infinite loop rather than a call on a main subprogram. 12.b
- The environment *declarative_part* at (1) is a sequence of *declarative_items* consisting of copies of the *library_items* included in the partition[]. The order of elaboration of *library_items* is the order in which they appear in the *environment declarative_part*]: 13
- The order of all included *library_items* is such that there are no forward elaboration dependences. 14
- Ramification:** This rule is written so that if a *library_item* depends on itself, we don't require it to be elaborated before itself. See AI83-00113/12. This can happen only in pathological circumstances. For example, if a *library subprogram_body* has no corresponding *subprogram_declaration*, and one of the subunits of the *subprogram_body* mentions the *subprogram_body* in a *with_clause*, the *subprogram_body* will depend on itself. For another example, if a *library_unit_body* applies a *pragma Elaborate_All* to its own declaration, then the *library_unit_body* will depend on itself. 14.a
- {AI05-0229-1} Any included *library_unit_declaration* for which aspect *Elaborate_Body* is True [(including when a *pragma Elaborate_Body* applies)] is immediately followed by its *library_unit_body*, if included. 15/3
- Discussion:** This implies that the body of such a library unit shall not “with” any of its own children, or anything else that depends semantically upon the declaration of the library unit. 15.a
- Proof:** {AI05-0229-1} *Pragma Elaborate_Body* sets aspect *Elaborate_Body*, see 10.2.1. 15.b/3
- All *library_items* declared pure occur before any that are not declared pure. 16

- 17 • All preelaborated `library_items` occur before any that are not preelaborated.
- 17.a **Discussion:** Normally, if two partitions contain the same compilation unit, they each contain a separate *copy* of that compilation unit. See Annex E, “Distributed Systems” for cases where two partitions share the same copy of something.
- 17.b There is no requirement that the main subprogram be elaborated last. In fact, it is possible to write a partition in which the main subprogram cannot be elaborated last.
- 17.c **Ramification:** This `declarative_part` has the properties required of all environments (see 10.1.4). However, the environment `declarative_part` of a partition will typically contain fewer compilation units than the environment `declarative_part` used at compile time — only the “needed” ones are included in the partition.
- 18 There shall be a total order of the `library_items` that obeys the above rules. The order is otherwise implementation defined.
- 18.a **Discussion:** The only way to violate this rule is to have `Elaborate`, `Elaborate_All`, or `Elaborate_Body` pragmas that cause circular ordering requirements, thus preventing an order that has no forward elaboration dependences.
- 18.b **Implementation defined:** The order of elaboration of `library_items`.
- 18.c **To be honest:** Notwithstanding what the RM95 says elsewhere, each rule that requires a declaration to have a corresponding completion is considered to be a Post-Compilation Rule when the declaration is that of a library unit.
- 18.d **Discussion:** Such rules may be checked at “link time,” for example. Rules requiring the completion to have certain properties, on the other hand, are checked at compile time of the completion.
- 19 The full expanded names of the library units and subunits included in a given partition shall be distinct.
- 19.a **Reason:** This is a Post-Compilation Rule because making it a Legality Rule would violate the Language Design Principle labeled “legality determinable via semantic dependences.”
- 20 The `sequence_of_statements` of the environment task (see (2) above) consists of either:
 - 21 • A call to the main subprogram, if the partition has one. If the main subprogram has parameters, they are passed; where the actuals come from is implementation defined. What happens to the result of a main function is also implementation defined.
 - 21.a **Implementation defined:** Parameter passing and function return for the main subprogram.
 - 22 or:
 - 23 • A `null_statement`, if there is no main subprogram.
 - 23.a **Discussion:** For a passive partition, either there is no environment task, or its `sequence_of_statements` is an infinite loop. See E.1.
- 24 The mechanisms for building and running partitions are implementation defined. [These might be combined into one operation, as, for example, in dynamic linking, or “load-and-go” systems.]
- 24.a **Implementation defined:** The mechanisms for building and running partitions.

Dynamic Semantics

- 25 The execution of a program consists of the execution of a set of partitions. Further details are implementation defined. The execution of a partition starts with the execution of its environment task, ends when the environment task terminates, and includes the executions of all tasks of the partition. [The execution of the (implicit) `task_body` of the environment task acts as a master for all other tasks created as part of the execution of the partition. When the environment task completes (normally or abnormally), it waits for the termination of all such tasks, and then finalizes any remaining objects of the partition.]
- 25.a **Ramification:** The “further details” mentioned above include, for example, program termination — it is implementation defined. There is no need to define it here; it’s entirely up to the implementation whether it wants to consider the program as a whole to exist beyond the existence of individual partitions.
- 25.b **Implementation defined:** The details of program execution, including program termination.
- 25.c **To be honest:** The execution of the partition terminates (normally or abnormally) when the environment task terminates (normally or abnormally, respectively).

Bounded (Run-Time) Errors

Once the environment task has awaited the termination of all other tasks of the partition, any further attempt to create a task (during finalization) is a bounded error, and may result in the raising of `Program_Error` either upon creation or activation of the task. If such a task is activated, it is not specified whether the task is awaited prior to termination of the environment task. 26

Implementation Requirements

The implementation shall ensure that all compilation units included in a partition are consistent with one another, and are legal according to the rules of the language. 27

Discussion: The consistency requirement implies that a partition cannot contain two versions of the same compilation unit. That is, a partition cannot contain two different library units with the same full expanded name, nor two different bodies for the same program unit. For example, suppose we compile the following: 27.a

```
package A is -- Version 1. 27.b
```

```
    ...
end A;
```

```
with A; 27.c
```

```
package B is
end B;
```

```
package A is -- Version 2. 27.d
```

```
    ...
end A;
```

```
with A; 27.e
```

```
package C is
end C;
```

It would be wrong for a partition containing B and C to contain both versions of A. Typically, the implementation would require the use of Version 2 of A, which might require the recompilation of B. Alternatively, the implementation might automatically recompile B when the partition is built. A third alternative would be an incremental compiler that, when Version 2 of A is compiled, automatically patches the object code for B to reflect the changes to A (if there are any relevant changes — there might not be any). 27.f

An implementation that supported fancy version management might allow the use of Version 1 in some circumstances. In no case can the implementation allow the use of both versions in the same partition (unless, of course, it can prove that the two versions are semantically identical). 27.g

The core language says nothing about inter-partition consistency; see also Annex E, “Distributed Systems”. 27.h

Implementation Permissions

{AI05-0299-1} The kind of partition described in this subclause is known as an *active* partition. An implementation is allowed to support other kinds of partitions, with implementation-defined semantics. 28/3

Implementation defined: The semantics of any nonactive partitions supported by the implementation. 28.a

Discussion: Annex E, “Distributed Systems” defines the concept of passive partitions; they may be thought of as a partition without an environment task, or as one with a particularly simple form of environment task, having an infinite loop rather than a call on a main subprogram as its `sequence_of_statements`. 28.b

An implementation may restrict the kinds of subprograms it supports as main subprograms. However, an implementation is required to support all main subprograms that are public parameterless library procedures. 29

Ramification: The implementation is required to support main subprograms that are procedures declared by `generic_instantiations`, as well as those that are children of library units other than `Standard`. Generic units are, of course, not allowed to be main subprograms, since they are not subprograms. 29.a

Note that renamings are irrelevant to this rule. This rule says which subprograms (not views) have to be supported. The implementation can choose any way it wants for the user to indicate which subprogram should be the main subprogram. An implementation might allow any name of any view, including those declared by renamings. Another implementation might require it to be the original name. Another implementation still might use the name of the source file or some such thing. 29.b

If the environment task completes abnormally, the implementation may abort any dependent tasks. 30

- 30.a **Reason:** If the implementation does not take advantage of this permission, the normal action takes place — the environment task awaits those tasks.
- 30.b The possibility of aborting them is not shown in the *Environment_Task* code above, because there is nowhere to put an `exception_handler` that can handle exceptions raised in both the `environment_declarative_part` and the main subprogram, such that the dependent tasks can be aborted. If we put an `exception_handler` in the body of the environment task, then it won't handle exceptions that occur during elaboration of the `environment_declarative_part`. If we were to move those things into a nested `block_statement`, with the `exception_handler` outside that, then the `block_statement` would await the library tasks we are trying to abort.
- 30.c Furthermore, this is merely a permission, and is not fundamental to the model, so it is probably better to state it separately anyway.
- 30.d Note that implementations (and tools like debuggers) can have modes that provide other behaviors in addition.

NOTES

- 31 8 An implementation may provide inter-partition communication mechanism(s) via special packages and pragmas. Standard pragmas for distribution and methods for specifying inter-partition communication are defined in Annex E, “Distributed Systems”. If no such mechanisms are provided, then each partition is isolated from all others, and behaves as a program in and of itself.
- 31.a **Ramification:** Not providing such mechanisms is equivalent to disallowing multi-partition programs.
- 31.b An implementation may provide mechanisms to facilitate checking the consistency of library units elaborated in different partitions; Annex E, “Distributed Systems” does so.
- 32 9 Partitions are not required to run in separate address spaces. For example, an implementation might support dynamic linking via the partition concept.
- 33 10 An order of elaboration of `library_items` that is consistent with the partial ordering defined above does not always ensure that each `library_unit_body` is elaborated before any other compilation unit whose elaboration necessitates that the `library_unit_body` be already elaborated. (In particular, there is no requirement that the body of a library unit be elaborated as soon as possible after the `library_unit_declaration` is elaborated, unless the pragmas in subclause 10.2.1 are used.)
- 34 11 A partition (active or otherwise) need not have a main subprogram. In such a case, all the work done by the partition would be done by elaboration of various `library_items`, and by tasks created by that elaboration. Passive partitions, which cannot have main subprograms, are defined in Annex E, “Distributed Systems”.
- 34.a **Ramification:** The environment task is the outermost semantic level defined by the language.
- 34.b Standard has no private part. This prevents strange implementation-dependences involving private children of Standard having visibility upon Standard's private part. It doesn't matter where the body of Standard appears in the environment, since it doesn't do anything. See Annex A, “Predefined Language Environment”.
- 34.c Note that elaboration dependence is carefully defined in such a way that if (say) the body of something doesn't exist yet, then there is no elaboration dependence upon the nonexistent body. (This follows from the fact that “needed by” is defined that way, and the elaboration dependences caused by a `pragma Elaborate` or `Elaborate_All` are defined in terms of “needed by”.) This property allows us to use the environment concept both at compile time and at partition-construction time/run time.

Extensions to Ada 83

- 34.d The concept of partitions is new to Ada 95.
- 34.e A main subprogram is now optional. The language-defined restrictions on main subprograms are relaxed.

Wording Changes from Ada 83

- 34.f Ada 95 uses the term “main subprogram” instead of Ada 83's “main program” (which was inherited from Pascal). This is done to avoid confusion — a main subprogram is a subprogram, not a program. The program as a whole is an entirely different thing.

Wording Changes from Ada 95

- 34.g/2 {AI95-00256-01} The mistaken use of “mentions” in the elaboration dependence rule was fixed.
- 34.h/2 {AI95-00217-06} The *needs* relationship was extended to include limited views.

10.2.1 Elaboration Control

- 1 [This subclause defines pragmas that help control the elaboration order of `library_items`.]

Language Design Principles

- The rules governing preelaboration are designed to allow it to be done largely by bulk initialization of statically allocated storage from information in a “load module” created by a linker. Some implementations may require run-time code to be executed in some cases, but we consider these cases rare enough that we need not further complicate the rules. 1.a
- It is important that programs be able to declare data structures that are link-time initialized with aggregates, string_literals, and concatenations thereof. It is important to be able to write link-time evaluated expressions involving the First, Last, and Length attributes of such data structures (including variables), because they might be initialized with positional aggregates or string_literals, and we don't want the user to have to count the elements. There is no corresponding need for accessing discriminants, since they can be initialized with a static constant, and then the constant can be referred to elsewhere. It is important to allow link-time initialized data structures involving discriminant-dependent components. It is important to be able to write link-time evaluated expressions involving pointers (both access values and addresses) to the above-mentioned data structures. 1.b
- The rules also ensure that no Elaboration_Check need be performed for calls on library-level subprograms declared within a preelaborated package. This is true also of the Elaboration_Check on task activation for library level task types declared in a preelaborated package. However, it is not true of the Elaboration_Check on instantiations. 1.c
- A static expression should never prevent a library unit from being preelaborable. 1.d
- Syntax*
- The form of a pragma Preelaborate is as follows: 2
- pragma** Preelaborate[(library_unit_name)]; 3
- A pragma Preelaborate is a library unit pragma. 4
- {AI95-00161-01} The form of a pragma Preelaborable_Initialization is as follows: 4.1/2
- pragma** Preelaborable_Initialization(direct_name); 4.2/2
- Legality Rules*
- An elaborable construct is preelaborable unless its elaboration performs any of the following actions: 5
- **Ramification:** A preelaborable construct can be elaborated without using any information that is available only at run time. Note that we don't try to prevent exceptions in preelaborable constructs; if the implementation wishes to generate code to raise an exception, that's OK. 5.a
 - Because there is no flow of control and there are no calls (other than to predefined subprograms), these run-time properties can actually be detected at compile time. This is necessary in order to require compile-time enforcement of the rules. 5.b
 - The execution of a statement other than a null_statement. 6
 - **Ramification:** A preelaborable construct can contain labels and null_statements. 6.a
 - A call to a subprogram other than a static function. 7
 - The evaluation of a primary that is a name of an object, unless the name is a static expression, or statically denotes a discriminant of an enclosing type. 8
 - **Ramification:** One can evaluate such a name, but not as a primary. For example, one can evaluate an attribute of the object. One can evaluate an attribute_reference, so long as it does not denote an object, and its prefix does not disobey any of these rules. For example, Obj'Access, Obj'Unchecked_Access, and Obj'Address are generally legal in preelaborated library units. 8.a
 - {AI95-00161-01} {AI05-0028-1} The creation of an object [(including a component)] that is initialized by default, if its type does not have preelaborable initialization. Similarly, the evaluation of an extension_aggregate with an ancestor subtype_mark denoting a subtype of such a type. 9/3
 - **Ramification:** One can declare these kinds of types, but one cannot create objects of those types. 9.a
 - It is also nonpreelaborable to create an object if that will cause the evaluation of a default expression that will call a user-defined function. This follows from the rule above forbidding nonnull statements. 9.b
 - *This paragraph was deleted. {AI95-00161-01}* 9.c/2

- 10/2 {AI95-00403-01} A generic body is preelaborable only if elaboration of a corresponding instance body would not perform any such actions, presuming that:
- 10.1/3 • {AI95-00403-01} {AI95-0028-1} the actual for each discriminated formal derived type, formal private type, or formal private extension declared within the formal part of the generic unit is a type that does not have preelaborable initialization, unless `pragma Preelaborable_Initialization` has been applied to the formal type;
 - 10.2/2 • {AI95-00403-01} the actual for each formal type is nonstatic;
 - 10.3/2 • {AI95-00403-01} the actual for each formal object is nonstatic; and
 - 10.4/2 • {AI95-00403-01} the actual for each formal subprogram is a user-defined subprogram.
- 10.a.1/2 **Discussion:** {AI95-00403-01} This is an “assume-the-worst” rule. The elaboration of a generic unit doesn't perform any of the actions listed above, because its sole effect is to establish that the generic can from now on be instantiated. So the elaboration of the generic itself is not the interesting part when it comes to preelaboration rules. The interesting part is what happens when you elaborate “any instantiation” of the generic. For instance, declaring an object of a limited formal private type might well start tasks, call functions, and do all sorts of nonpreelaborable things. We prevent these situations by assuming that the actual parameters are as badly behaved as possible.
- 10.a **Reason:** Without this rule about generics, we would have to forbid instantiations in preelaborated library units, which would significantly reduce their usefulness.
- 11/3 {8652/0035} {AI95-00002-01} {AI05-0034-1} {AI05-0243-1} A `pragma Preelaborate` (or `pragma Pure` — see below) is used to specify that a library unit is *preelaborated*, namely that the `Preelaborate` aspect of the library unit is `True`; all compilation units of the library unit are preelaborated. The declaration and body of a preelaborated library unit, and all subunits that are elaborated as part of elaborating the library unit, shall be preelaborable. All compilation units of a preelaborated library unit shall depend semantically only on declared pure or preelaborated `library_items`. In addition to the places where Legality Rules normally apply (see 12.3), these rules also apply in the private part of an instance of a generic unit. [If a library unit is preelaborated, then its declaration, if any, and body, if any, are elaborated prior to all nonpreelaborated `library_items` of the partition.]
- 11.a **Ramification:** In a generic body, we assume the worst about formal private types and extensions.
- 11.a.1/1 {8652/0035} {AI95-00002-01} Subunits of a preelaborated subprogram unit do not need to be preelaborable. This is needed in order to be consistent with units nested in a subprogram body, which do not need to be preelaborable even if the subprogram is preelaborated. However, such subunits cannot depend semantically on nonpreelaborated units, which is also consistent with nested units.
- 11.b/3 **Aspect Description for `Preelaborate`:** Code execution during elaboration is avoided for a given package.
- 11.1/2 {AI95-00161-01} The following rules specify which entities have *preelaborable initialization*:
- 11.2/3 • {AI05-0028-1} The partial view of a private type or private extension, a protected type without `entry_declarations`, a generic formal private type, or a generic formal derived type, has preelaborable initialization if and only if the `pragma Preelaborable_Initialization` has been applied to them. [A protected type with `entry_declarations` or a task type never has preelaborable initialization.]
 - 11.3/2 • A component (including a discriminant) of a record or protected type has preelaborable initialization if its declaration includes a `default_expression` whose execution does not perform any actions prohibited in preelaborable constructs as described above, or if its declaration does not include a default expression and its type has preelaborable initialization.
 - 11.4/3 • {AI05-0028-1} {AI05-0221-1} A derived type has preelaborable initialization if its parent type has preelaborable initialization and if the noninherited components all have preelaborable initialization. However, a controlled type with an `Initialize` procedure that is not a null procedure does not have preelaborable initialization.

- *{AI95-00161-01}* *{AI95-00345-01}* A view of a type has preelaborable initialization if it is an elementary type, an array type whose component type has preelaborable initialization, a record type whose components all have preelaborable initialization, or an interface type. 11.5/2
- {AI95-00161-01}* A **pragma** `Preelaborable_Initialization` specifies that a type has preelaborable initialization. This pragma shall appear in the visible part of a package or generic package. 11.6/2
- {AI95-00161-01}* *{AI95-00345-01}* *{AI05-0028-1}* If the pragma appears in the first list of `basic_declarative_items` of a `package_specification`, then the `direct_name` shall denote the first subtype of a composite type, and the type shall be declared immediately within the same package as the pragma. If the pragma is applied to a private type or a private extension, the full view of the type shall have preelaborable initialization. If the pragma is applied to a protected type, the protected type shall not have entries, and each component of the protected type shall have preelaborable initialization. For any other composite type, the type shall have preelaborable initialization. In addition to the places where Legality Rules normally apply (see 12.3), these rules apply also in the private part of an instance of a generic unit. 11.7/3
- Reason:** *{AI05-0028-1}* The reason why we need the pragma for private types, private extensions, and protected types is fairly clear: the properties of the full view determine whether the type has preelaborable initialization or not; in order to preserve privacy we need a way to express on the partial view that the full view is well-behaved. The reason why we need the pragma for other composite types is more subtle: a nonnull override for `Initialize` might occur in the private part, even for a nonprivate type; in order to preserve privacy, we need a way to express on a type declared in a visible part that the private part does not contain any nasty override of `Initialize`. 11.c/3
- {AI95-00161-01}* If the pragma appears in a `generic_formal_part`, then the `direct_name` shall denote a generic formal private type or a generic formal derived type declared in the same `generic_formal_part` as the pragma. In a `generic_instantiation` the corresponding actual type shall have preelaborable initialization. 11.8/2
- Ramification:** Not only do protected types with `entry_declarations` and task types not have preelaborable initialization, but they cannot have pragma `Preelaborable_Initialization` applied to them. 11.d/2
- Implementation Advice*
- In an implementation, a type declared in a preelaborated package should have the same representation in every elaboration of a given version of the package, whether the elaborations occur in distinct executions of the same program, or in executions of distinct programs or partitions that include the given version. 12
- Implementation Advice:** A type declared in a preelaborated package should have the same representation in every elaboration of a given version of the package. 12.a/2
- Syntax*
- The form of a pragma `Pure` is as follows: 13
- pragma** `Pure`[(*library_unit_name*)]; 14
- A pragma `Pure` is a library unit pragma. 15
- Static Semantics*
- {AI95-00366-01}* *{AI05-0035-1}* A *pure* compilation unit is a preelaborable compilation unit whose elaboration does not perform any of the following actions: 15.1/3
- the elaboration of a variable declaration; 15.2/2
 - the evaluation of an `allocator` of an access-to-variable type; for the purposes of this rule, the partial view of a type is presumed to have nonvisible components whose default initialization evaluates such an `allocator`; 15.3/2
- Reason:** *{AI05-0004-1}* Such an `allocator` would provide a backdoor way to get a global variable into a pure unit, so it is prohibited. Most such `allocators` are illegal anyway, as their type is required to have `Storage_Size = 0` (see the next two rules). But access parameters and access discriminants don't necessarily disallow `allocators`. However, a call is 15.a.1/3

also illegal here (by the preelaboration rules), so access parameters cannot cause trouble. So this rule is really about prohibiting allocators in discriminant constraints:

- 15.a.2/3 `type Rec (Acc : access Integer) is record`
 `C : Character;`
 `end record;`
- 15.a.3/3 `Not_Const : constant Rec (Acc => new Integer'(2)); -- Illegal in a pure unit.`
- 15.a/3 {AI05-0004-1} The second half of the rule is needed because aggregates can specify the default initialization of a private type or extension using `<>` or the ancestor subtype of an extension aggregate. The subtype of a component could use an allocator to initialize an access discriminant; the type still could have a pragma `Preelaborable_Initialization` given. Ada 95 did not allow such private types to have preelaborable initialization, so such a default initialization could not have occurred. Thus this rule is not incompatible with Ada 95.
- 15.4/3 • {AI05-0035-1} the elaboration of the declaration of a nonderived named access-to-variable type unless the `Storage_Size` of the type has been specified by a static expression with value zero or is defined by the language to be zero;
- 15.b/2 **Discussion:** A remote access-to-class-wide type (see E.2.2) has its `Storage_Size` defined to be zero.
- 15.c/2 **Reason:** {AI95-00366-01} We disallow most named access-to-object types because an allocator has a side effect; the pool constitutes variable data. We allow access-to-subprogram types because they don't have allocators. We even allow named access-to-object types if they have an empty predefined pool (they can't have a user-defined pool as `System.Storage_Pools` is not pure). In this case, most attempts to use an allocator are illegal, and any others (in a generic body) will raise `Storage_Error`.
- 15.5/3 • {AI05-0035-1} the elaboration of the declaration of a nonderived named access-to-constant type for which the `Storage_Size` has been specified by an expression other than a static expression with value zero.
- 15.d/2 **Discussion:** We allow access-to-constant types so long as there is no user-specified nonzero `Storage_Size`; if there were a user-specified nonzero `Storage_Size` restricting the size of the storage pool, allocators would be problematic since the package is supposedly 'stateless', and the allocated size count for the storage pool would represent state.
- 15.6/3 {AI05-0035-1} A generic body is pure only if elaboration of a corresponding instance body would not perform any such actions presuming any composite formal types have nonvisible components whose default initialization evaluates an allocator of an access-to-variable type.
- 15.7/2 {AI95-00366-01} The `Storage_Size` for an anonymous access-to-variable type declared at library level in a library unit that is declared pure is defined to be zero.
- 15.e/2 **Ramification:** This makes allocators illegal for such types (see 4.8), making a storage pool unnecessary for these types. A storage pool would represent state.
- 15.f/2 Note that access discriminants and access parameters are never library-level, even when they are declared in a type or subprogram declared at library-level. That's because they have their own special accessibility rules (see 3.10.2).

Legality Rules

- 16/2 This paragraph was deleted. {AI95-00366-01}
- 17/3 {AI95-00366-01} {AI05-0034-1} {AI05-0035-1} {AI05-0243-1} A pragma `Pure` is used to specify that a library unit is *declared pure*, namely that the `Pure` aspect of the library unit is `True`; all compilation units of the library unit are declared pure. In addition, the limited view of any library package is declared pure. The declaration and body of a declared pure library unit, and all subunits that are elaborated as part of elaborating the library unit, shall be pure. All compilation units of a declared pure library unit shall depend semantically only on declared pure `library_items`. In addition to the places where Legality Rules normally apply (see 12.3), these rules also apply in the private part of an instance of a generic unit. Furthermore, the full view of any partial view declared in the visible part of a declared pure library unit that has any available stream attributes shall support external streaming (see 13.13.2).
- 17.a/3 This paragraph was deleted. {AI05-0243-1}
- 17.b **Discussion:** A declared-pure package is useful for defining types to be shared between partitions with no common address space.

Reason: Note that generic packages are not mentioned in the list of things that can contain variable declarations. Note that the Ada 95 rules for deferred constants make them allowable in library units that are declared pure; that isn't true of Ada 83's deferred constants.	17.c
Ramification: <i>{AI95-00366-01}</i> Anonymous access types are allowed.	17.d/2
<i>{AI05-0243-1}</i> A limited view is not a library unit, so any rule that starts “declared pure library unit” does not apply to a limited view. In particular, the 3rd and last sentences never apply to limited views. However, a limited view is a <code>library_item</code> , so rules that discuss “declared pure <code>library_items</code> ” do include limited views.	17.d.1/3
Reason: <i>{AI95-00366-01}</i> Ada 95 didn't allow any access types as these (including access-to-subprogram types) cause trouble for Annex E, “Distributed Systems”, because such types allow access values in a shared passive partition to designate objects in an active partition, thus allowing inter-address space references. We decided to disallow such uses in the relatively rare cases where they cause problems, rather than making life harder for the majority of users. Types declared in a pure package can be used in remote operations only if they are externally streamable. That simply means that there is a means to transport values of the type; that's automatically true for nonlimited types that don't have an access part. The only tricky part about this is to avoid privacy leakage; that was handled by ensuring that any private types (and private extensions) declared in a pure package that have available stream attributes (which include all nonlimited types by definition) have to be externally streamable.	17.e/2
Aspect Description for Pure: Side effects are avoided in the subprograms of a given package.	17.f/3
<i>Implementation Permissions</i>	
<i>{AI95-00366-01}</i> <i>{AI05-0219-1}</i> If a library unit is declared pure, then the implementation is permitted to omit a call on a library-level subprogram of the library unit if the results are not needed after the call. In addition, the implementation may omit a call on such a subprogram and simply reuse the results produced by an earlier call on the same subprogram, provided that none of the parameters nor any object accessible via access values from the parameters have any part that is of a type whose full type is an immutably limited type, and the addresses and values of all by-reference actual parameters, the values of all by-copy-in actual parameters, and the values of all objects accessible via access values from the parameters, are the same as they were at the earlier call. [This permission applies even if the subprogram produces other side effects when called.]	18/3
Discussion: <i>{AI95-00366-01}</i> <i>{AI05-0005-1}</i> <i>{AI05-0299-1}</i> A declared-pure <code>library_item</code> has no variable state. Hence, a call on one of its (nonnested) subprograms cannot normally have side effects. Side effects are still possible via dispatching calls and via indirect calls through access-to-subprogram values. Other mechanisms that might be used to modify variable state include machine code insertions, imported subprograms, and unchecked conversion to an access type declared within the subprogram; this list is not exhaustive. Thus, the permissions described in this subclause may apply to a subprogram whose execution has side effects. The compiler may omit a call to such a subprogram even if side effects exist, so the writer of such a subprogram has to keep this in mind.	18.a/3
<i>Syntax</i>	
The form of a <code>pragma Elaborate</code> , <code>Elaborate_All</code> , or <code>Elaborate_Body</code> is as follows:	19
pragma <code>Elaborate</code> (<i>library_unit_name</i> {, <i>library_unit_name</i> });	20
pragma <code>Elaborate_All</code> (<i>library_unit_name</i> {, <i>library_unit_name</i> });	21
pragma <code>Elaborate_Body</code> [(<i>library_unit_name</i>)];	22
A <code>pragma Elaborate</code> or <code>Elaborate_All</code> is only allowed within a <code>context_clause</code> .	23
Ramification: “Within a <code>context_clause</code> ” allows it to be the last item in the <code>context_clause</code> . It can't be first, because the name has to denote something mentioned earlier.	23.a
A <code>pragma Elaborate_Body</code> is a library unit pragma.	24
Discussion: Hence, a <code>pragma Elaborate</code> or <code>Elaborate_All</code> is not elaborated, not that it makes any practical difference.	24.a
Note that a <code>pragma Elaborate</code> or <code>Elaborate_All</code> is neither a program unit pragma, nor a library unit pragma.	24.b
<i>Legality Rules</i>	
<i>{AI05-0229-1}</i> If the aspect <code>Elaborate_Body</code> is True for a declaration [(including when <code>pragma Elaborate_Body</code> applies)], then the declaration requires a completion [(a body)].	25/3

- 25.a/3 **Proof:** {AI05-0229-1} Pragma Elaborate_Body sets the aspect (see below).
- 25.1/2 {AI95-00217-06} The *library_unit_name* of a pragma Elaborate or Elaborate_All shall denote a nonlimited view of a library unit.
- 25.b/2 **Reason:** These pragmas are intended to prevent elaboration check failures. But a limited view does not make anything visible that has an elaboration check, so the pragmas cannot do anything useful. Moreover, the pragmas would probably reintroduce the circularity that the *limited_with_clause* was intended to break. So we make such uses illegal.

Static Semantics

- 26/3 {AI05-0229-1} [A pragma Elaborate specifies that the body of the named library unit is elaborated before the current *library_item*. A pragma Elaborate_All specifies that each *library_item* that is needed by the named library unit declaration is elaborated before the current *library_item*.]
- 26.a **Proof:** The official statement of the semantics of these pragmas is given in 10.2.
- 26.1/3 {AI05-0229-1} A pragma Elaborate_Body sets the Elaborate_Body representation aspect of the library unit to which it applies to the value True. [If the Elaborate_Body aspect of a library unit is True, the body of the library unit is elaborated immediately after its declaration.]
- 26.a.1/3 **Proof:** The official statement of the semantics of this aspect is given in 10.2.
- 26.b **Implementation Note:** The presence of a pragma Elaborate_Body simplifies the removal of unnecessary Elaboration_Checks. For a subprogram declared immediately within a library unit to which a pragma Elaborate_Body applies, the only calls that can fail the Elaboration_Check are those that occur in the library unit itself, between the declaration and body of the called subprogram; if there are no such calls (which can easily be detected at compile time if there are no stubs), then no Elaboration_Checks are needed for that subprogram. The same is true for Elaboration_Checks on task activations and instantiations, and for library subprograms and generic units.
- 26.c **Ramification:** The fact that the unit of elaboration is the *library_item* means that if a *subprogram_body* is not a completion, it is impossible for any *library_item* to be elaborated between the declaration and the body of such a subprogram. Therefore, it is impossible for a call to such a subprogram to fail its Elaboration_Check.
- 26.d **Discussion:** The visibility rules imply that each *library_unit_name* of a pragma Elaborate or Elaborate_All has to denote a library unit mentioned by a previous *with_clause* of the same *context_clause*.
- 26.e/3 **Aspect Description for Elaborate_Body:** A given package must have a body, and that body is elaborated immediately after the declaration.

NOTES

- 27 12 A preelaborated library unit is allowed to have nonpreelaborable children.
- 27.a/1 **Ramification:** {8652/0035} {AI95-00002-01} But generally not nonpreelaborated subunits. (Nonpreelaborated subunits of subprograms are allowed as discussed above.)
- 28 13 A library unit that is declared pure is allowed to have impure children.
- 28.a/1 **Ramification:** {8652/0035} {AI95-00002-01} But generally not impure subunits. (Impure subunits of subprograms are allowed as discussed above.)
- 28.b **Ramification:** Pragma Elaborate is mainly for closely related library units, such as when two package bodies 'with' each other's declarations. In such cases, Elaborate_All sometimes won't work.

Extensions to Ada 83

- 28.c The concepts of preelaborability and purity are new to Ada 95. The Elaborate_All, Elaborate_Body, Preelaborate, and Pure pragmas are new to Ada 95.
- 28.d Pragmas Elaborate are allowed to be mixed in with the other things in the *context_clause* — in Ada 83, they were required to appear last.

Incompatibilities With Ada 95

- 28.e/2 {AI95-00366-01} The requirement that a partial view with available stream attributes be externally streamable can cause an incompatibility in rare cases. If there is a limited tagged type declared in a pure package with available attributes, and that type is used to declare a private extension in another pure package, and the full type for the private extension has a component of an explicitly limited record type, a protected type, or a type with access discriminants, then the stream attributes will have to be user-specified in the visible part of the package. That is not a requirement for Ada 95, but this combination seems very unlikely in pure packages. Note that this cannot be an incompatibility for a

nonlimited type, as all of the types that are allowed in Ada 95 that would require explicitly defined stream attributes are limited (and thus cannot be used as components in a nonlimited type).

{AI95-00403-01} **Amendment Correction:** Added wording to cover missing cases for preelaborated generic units. This is incompatible as a preelaborated unit could have used a formal object to initialize a library-level object; that isn't allowed in Ada 2005. But such a unit wouldn't really be preelaborable, and Ada 95 compilers can reject such units (as this is a Binding Interpretation), so such units should be very rare. 28.f/2

Extensions to Ada 95

{AI95-00161-01} **Amendment Correction:** The concept of preelaborable initialization and pragma Preelaborable Initialization are new. These allow more types of objects to be created in preelaborable units, and fix holes in the old rules. 28.g/2

{AI95-00366-01} Access-to-subprogram types and access-to-object types with a Storage_Size of 0 are allowed in pure units. The permission to omit calls was adjusted accordingly (which also fixes a hole in Ada 95, as access parameters are allowed, and changes in the values accessed by them must be taken into account). 28.h/2

Wording Changes from Ada 95

{AI95-00002-01} **Corrigendum:** The wording was changed so that subunits of a preelaborated subprogram are also preelaborated. 28.i/2

{AI95-00217-06} Disallowed pragma Elaborate and Elaborate_All for packages that are mentioned in a limited_with_clause. 28.j/2

Incompatibilities With Ada 2005

{AI05-0028-1} **Correction:** Corrected a serious unintended incompatibility with Ada 95 in the new preelaboration wording — explicit initialization of objects of types that don't have preelaborable initialization was not allowed. Ada 2012 switches back to the Ada 95 rule in these cases. This is unlikely to occur in practice, as it is unlikely that a compiler would have implemented the more restrictive rule (it would fail many ACATS tests if it did). 28.k/3

{AI05-0035-1} **Correction:** Added an assume-the-worst rule for generic bodies (else they would never be checked for purity) and added the boilerplate so that the entire generic specification is rechecked. Also fixed wording to have consistent handling for subunits for Pure and Preelaborate. An Ada 95 program could have depended on marking a generic pure that was not really pure, although this would defeat the purpose of the categorization and likely cause problems with distributed programs. 28.l/3

Extensions to Ada 2005

{AI05-0035-1} **Correction:** Adjusted wording so that a subunit can be pure (it is not a library_item, but it is a compilation unit). 28.m/3

{AI05-0035-1} **Correction:** Adjusted wording so that the rules for access types only apply to nonderived types (derived types share their storage pool with their parent, so if the parent access type is legal, so is any derived type.) 28.n/3

{AI05-0229-1} Elaborate_Body is now an aspect, so it can be specified by an aspect_specification — although the pragma is still preferred by the Standard. 28.o/3

{AI05-0243-1} Pure and Preelaborate are now aspects, so they can be specified by an aspect_specification — although the pragmas are still preferred by the Standard. 28.p/3

Wording Changes from Ada 2005

{AI05-0034-1} **Correction:** Added wording so that a limited view is always treated as pure, no matter what categorization is used for the originating unit. This was undefined in Ada 2005. 28.q/3

{AI05-0028-1} {AI05-0221-1} **Correction:** Fixed minor issues with preelaborable initialization (PI): null Initialize procedures do not make a type non-PI; formal types with pragma PI can be assumed to have PI; formal extensions are assumed to not have PI; all composite types can have pragma PI (so that the possibility of hidden Initialize routines can be handled); added discriminants of a derived type are not considered in calculating PI. 28.r/3

{AI05-0219-1} **Correction:** Clarified that the implementation permission to omit pure subprogram calls does not apply if any part of the parameters or any designated object has a part that is immutably limited. The old wording just said "limited type", which can change via visibility and thus isn't appropriate for dynamic semantics permissions. 28.s/3

11 Exceptions

{AI05-0299-1} [This clause defines the facilities for dealing with errors or other exceptional situations that arise during program execution.] An *exception* represents a kind of exceptional situation; an occurrence of such a situation (at run time) is called an *exception occurrence*. [To *raise* an exception is to abandon normal program execution so as to draw attention to the fact that the corresponding situation has arisen. Performing some actions in response to the arising of an exception is called *handling* the exception.] 1/3

To be honest: ...or handling the exception occurrence. 1.a

Ramification: For example, an exception `End_Error` might represent error situations in which an attempt is made to read beyond end-of-file. During the execution of a partition, there might be numerous occurrences of this exception. 1.b

To be honest: When the meaning is clear from the context, we sometimes use “*occurrence*” as a short-hand for “exception occurrence.” 1.c

{AI05-0043-1} {AI05-0258-1} [An `exception_declaration` declares a name for an exception. An exception can be raised explicitly (for example, by a `raise_statement`) or implicitly (for example, by the failure of a language-defined check). When an exception arises, control can be transferred to a user-provided `exception_handler` at the end of a `handled_sequence_of_statements`, or it can be propagated to a dynamically enclosing execution.] 2/3

Wording Changes from Ada 83

We are more explicit about the difference between an exception and an occurrence of an exception. This is necessary because we now have a type (`Exception_Occurrence`) that represents exception occurrences, so the program can manipulate them. Furthermore, we say that when an exception is propagated, it is the same occurrence that is being propagated (as opposed to a new occurrence of the same exception). The same issue applies to a re-raise statement. In order to understand these semantics, we have to make this distinction. 2.a

Wording Changes from Ada 2005

{AI05-0043-1} **Correction:** Generalized the introductory description of how an exception can be raised so that it does not appear to cover all of the cases. 2.b/3

11.1 Exception Declarations

An `exception_declaration` declares a name for an exception. 1

Syntax

{AI05-0183-1} `exception_declaration ::= defining_identifier_list : exception`
`[aspect_specification];` 2/3

Static Semantics

Each single `exception_declaration` declares a name for a different exception. If a generic unit includes an `exception_declaration`, the `exception_declarations` implicitly generated by different instantiations of the generic unit refer to distinct exceptions (but all have the same `defining_identifier`). The particular exception denoted by an exception name is determined at compilation time and is the same regardless of how many times the `exception_declaration` is elaborated. 3

Reason: We considered removing this requirement inside generic bodies, because it is an implementation burden for implementations that wish to share code among several instances. In the end, it was decided that it would introduce too much implementation dependence. 3.a

Ramification: Hence, if an `exception_declaration` occurs in a recursive subprogram, the exception name denotes the same exception for all invocations of the recursive subprogram. The reason for this rule is that we allow an exception occurrence to propagate out of its declaration's innermost containing master; if exceptions were created by their 3.b

declarations like other entities, they would presumably be destroyed upon leaving the master; we would have to do something special to prevent them from propagating to places where they no longer exist.

3.c **Ramification:** Exception identities are unique across all partitions of a program.

4 The *predefined* exceptions are the ones declared in the declaration of package Standard: Constraint_Error, Program_Error, Storage_Error, and Tasking_Error[]; one of them is raised when a language-defined check fails.]

4.a **Ramification:** The exceptions declared in the language-defined package IO_Exceptions, for example, are not predefined.

Dynamic Semantics

5 The elaboration of an `exception_declaration` has no effect.

6 The execution of any construct raises `Storage_Error` if there is insufficient storage for that execution. The amount of storage needed for the execution of constructs is unspecified.

6.a **Ramification:** Note that any execution whatsoever can raise `Storage_Error`. This allows much implementation freedom in storage management.

Examples

7 *Examples of user-defined exception declarations:*

```
8 Singular : exception;
   Error   : exception;
   Overflow, Underflow : exception;
```

Inconsistencies With Ada 83

8.a The exception `Numeric_Error` is now defined in the Obsolescent features Annex, as a rename of `Constraint_Error`. All checks that raise `Numeric_Error` in Ada 83 instead raise `Constraint_Error` in Ada 95. To increase upward compatibility, we also changed the rules to allow the same exception to be named more than once by a given handler. Thus, “**when** `Constraint_Error | Numeric_Error =>`” will remain legal in Ada 95, even though `Constraint_Error` and `Numeric_Error` now denote the same exception. However, it will not be legal to have separate handlers for `Constraint_Error` and `Numeric_Error`. This change is inconsistent in the rare case that an existing program explicitly raises `Numeric_Error` at a point where there is a handler for `Constraint_Error`; the exception will now be caught by that handler.

Wording Changes from Ada 83

8.b We explicitly define elaboration for `exception_declarations`.

Extensions to Ada 2005

8.c/3 {AI05-0183-1} An optional `aspect_specification` can be used in a `exception_declaration`. This is described in 13.1.1.

11.2 Exception Handlers

1 [The response to one or more exceptions is specified by an `exception_handler`.]

Syntax

```
2 handled_sequence_of_statements ::=
   sequence_of_statements
   [exception
    exception_handler
    {exception_handler}]
3 exception_handler ::=
   when [choice_parameter_specification:] exception_choice { | exception_choice } =>
   sequence_of_statements
4 choice_parameter_specification ::= defining_identifier
```

`exception_choice ::= exception_name | others` 5

To be honest: “*Handler*” is an abbreviation for “`exception_handler`.” 5.a

{A105-0299-1} Within this clause, we sometimes abbreviate “`exception_choice`” to “*choice*.” 5.b/3

Legality Rules

A choice with an *exception_name* covers the named exception. A choice with **others** covers all exceptions not named by previous choices of the same `handled_sequence_of_statements`. Two choices in different `exception_handlers` of the same `handled_sequence_of_statements` shall not cover the same exception. 6

Ramification: Two `exception_choices` of the same `exception_handler` may cover the same exception. For example, given two renaming declarations in separate packages for the same exception, one may nevertheless write, for example, “`when Ada.Text_IO.Data_Error | My_Seq_IO.Data_Error =>`”. 6.a

An **others** choice even covers exceptions that are not visible at the place of the handler. Since exception raising is a dynamic activity, it is entirely possible for an **others** handler to handle an exception that it could not have named. 6.b

A choice with **others** is allowed only for the last handler of a `handled_sequence_of_statements` and as the only choice of that handler. 7

An *exception_name* of a choice shall not denote an exception declared in a generic formal package. 8

Reason: This is because the compiler doesn't know the identity of such an exception, and thus can't enforce the coverage rules. 8.a

Static Semantics

A `choice_parameter_specification` declares a *choice parameter*, which is a constant object of type `Exception_Occurrence` (see 11.4.1). During the handling of an exception occurrence, the choice parameter, if any, of the handler represents the exception occurrence that is being handled. 9

Dynamic Semantics

The execution of a `handled_sequence_of_statements` consists of the execution of the `sequence_of_statements`. [The optional handlers are used to handle any exceptions that are propagated by the `sequence_of_statements`.] 10

Examples

Example of an exception handler: 11

```
begin
  Open(File, In_File, "input.txt"); -- see A.8.2
exception
  when E : Name_Error =>
    Put("Cannot open input file : ");
    Put_Line(Exception_Message(E)); -- see 11.4.1
  raise;
end;
```

12

Extensions to Ada 83

The syntax rule for `exception_handler` is modified to allow a `choice_parameter_specification`. 12.a

{A195-00114-01} Different `exception_choices` of the same `exception_handler` may cover the same exception. This allows for “`when Numeric_Error | Constraint_Error =>`” even though `Numeric_Error` is a rename of `Constraint_Error`. This also allows one to “`with`” two different I/O packages, and then write, for example, “`when Ada.Text_IO.Data_Error | My_Seq_IO.Data_Error =>`” even though these might both be renames of the same exception. 12.b/2

Wording Changes from Ada 83

- 12.c The syntax rule for `handled_sequence_of_statements` is new. These are now used in all the places where handlers are allowed. This obviates the need to explain (in Clauses 5, 6, 7, and 9) what portions of the program are handled by the handlers. Note that there are more such cases in Ada 95.
- 12.d The syntax rule for `choice_parameter_specification` is new.

11.3 Raise Statements

- 1 [A `raise_statement` raises an exception.]

Syntax

- 2/2 `{AI95-00361-01} raise_statement ::= raise;`
`| raise exception_name [with string_expression];`

Legality Rules

- 3 The name, if any, in a `raise_statement` shall denote an exception. A `raise_statement` with no `exception_name` (that is, a *re-raise statement*) shall be within a handler, but not within a body enclosed by that handler.

Name Resolution Rules

- 3.1/2 `{AI95-00361-01}` The expression, if any, in a `raise_statement`, is expected to be of type `String`.

Dynamic Semantics

- 4/2 `{AI95-00361-01}` To *raise an exception* is to raise a new occurrence of that exception[, as explained in 11.4]. For the execution of a `raise_statement` with an `exception_name`, the named exception is raised. [If a `string_expression` is present, the expression is evaluated and its value is associated with the exception occurrence.] For the execution of a re-raise statement, the exception occurrence that caused transfer of control to the innermost enclosing handler is raised [again].
- 4.a.1/2 **Proof:** `{AI95-00361-01}` The definition of `Exceptions.Exception_Message` includes a statement that the string is returned (see 11.4.1). We describe the use of the string here so that we don't have an unexplained parameter in this subclause.
- 4.a **Implementation Note:** For a re-raise statement, the implementation does not create a new `Exception_Occurrence`, but instead propagates the same `Exception_Occurrence` value. This allows the original cause of the exception to be determined.

Examples

- 5 *Examples of raise statements:*

- 6/2 `{AI95-00433-01} raise Ada.IO_Exceptions.Name_Error; -- see A.13`
`raise Queue_Error with "Buffer Full"; -- see 9.11`
- 7 `raise;` *-- re-raise the current exception*

Wording Changes from Ada 83

- 7.a The fact that the name in a `raise_statement` has to denote an exception is not clear from RM83. Clearly that was the intent, since the italicized part of the syntax rules so indicate, but there was no explicit rule. RM83-1.5(11) doesn't seem to give the italicized parts of the syntax any force.

Extensions to Ada 95

- 7.b/2 `{AI95-00361-01}` The syntax of a `raise_statement` is extended to include a string message. This is more convenient than calling `Exceptions.Exception_Message(exception_name'Identity, string_expression)`, and should encourage the use of message strings when raising exceptions.

11.4 Exception Handling

[When an exception occurrence is raised, normal program execution is abandoned and control is transferred to an applicable `exception_handler`, if any. To *handle* an exception occurrence is to respond to the exceptional event. To *propagate* an exception occurrence is to raise it again in another context; that is, to fail to respond to the exceptional event in the present context.] 1

Ramification: In other words, if the execution of a given construct raises an exception, but does not handle it, the exception is propagated to an enclosing execution (except in the case of a `task_body`). 1.a

Propagation involves re-raising the same exception occurrence. For example, calling an entry of an uncallable task raises `Tasking_Error`; this is not propagation. 1.b/1

Dynamic Semantics

Within a given task, if the execution of construct *a* is defined by this International Standard to consist (in part) of the execution of construct *b*, then while *b* is executing, the execution of *a* is said to *dynamically enclose* the execution of *b*. The *innermost dynamically enclosing* execution of a given execution is the dynamically enclosing execution that started most recently. 2

To be honest: If the execution of *a* dynamically encloses that of *b*, then we also say that the execution of *b* is *included in* the execution of *a*. 2.a

Ramification: Examples: The execution of an `if_statement` dynamically encloses the evaluation of the condition after the `if` (during that evaluation). (Recall that “execution” includes both “elaboration” and “evaluation”, as well as other executions.) The evaluation of a function call dynamically encloses the execution of the `sequence_of_statements` of the function body (during that execution). Note that, due to recursion, several simultaneous executions of the same construct can be occurring at once during the execution of a particular task. 2.b

Dynamically enclosing is not defined across task boundaries; a task's execution does not include the execution of any other tasks. 2.c

Dynamically enclosing is only defined for executions that are occurring at a given moment in time; if an `if_statement` is currently executing the `sequence_of_statements` after `then`, then the evaluation of the condition is no longer dynamically enclosed by the execution of the `if_statement` (or anything else). 2.d

When an exception occurrence is raised by the execution of a given construct, the rest of the execution of that construct is *abandoned*; that is, any portions of the execution that have not yet taken place are not performed. The construct is first completed, and then left, as explained in 7.6.1. Then: 3

- If the construct is a `task_body`, the exception does not propagate further; 4

Ramification: When an exception is raised by the execution of a `task_body`, there is no dynamically enclosing execution, so the exception does not propagate any further. If the exception occurred during the activation of the task, then the activator raises `Tasking_Error`, as explained in 9.2, “Task Execution - Task Activation”, but we don't define that as propagation; it's a special rule. Otherwise (the exception occurred during the execution of the `handled_sequence_of_statements` of the task), the task silently disappears. Thus, abnormal termination of tasks is not always considered to be an error. 4.a

- If the construct is the `sequence_of_statements` of a `handled_sequence_of_statements` that has a handler with a choice covering the exception, the occurrence is handled by that handler; 5

- Otherwise, the occurrence is *propagated* to the innermost dynamically enclosing execution, which means that the occurrence is raised again in that context. 6

To be honest: As shorthands, we refer to the *propagation of an exception*, and the *propagation by a construct*, if the execution of the construct propagates an exception occurrence. 6.a

When an occurrence is *handled* by a given handler, the `choice_parameter_specification`, if any, is first elaborated, which creates the choice parameter and initializes it to the occurrence. Then, the `sequence_of_statements` of the handler is executed; this execution replaces the abandoned portion of the execution of the `sequence_of_statements`. 7

- 7.a/2 **Ramification:** {AI95-00318-02} This “replacement” semantics implies that the handler can do pretty much anything the abandoned sequence could do; for example, in a function, the handler can execute a return statement that applies to the function.
- 7.b **Ramification:** The rules for exceptions raised in library units, main subprograms and partitions follow from the normal rules, plus the semantics of the environment task described in Clause 10 (for example, the environment task of a partition elaborates library units and calls the main subprogram). If an exception is propagated by the main subprogram, it is propagated to the environment task, which then terminates abnormally, causing the partition to terminate abnormally. Although abnormal termination of tasks is not necessarily an error, abnormal termination of a partition due to an exception *is* an error.
- NOTES
- 8 1 Note that exceptions raised in a `declarative_part` of a body are not handled by the handlers of the `handled_sequence_of_statements` of that body.

11.4.1 The Package Exceptions

Static Semantics

- 1 The following language-defined library package exists:
- 2/2 {AI95-00362-01} {AI95-00400-01} {AI95-00438-01} **with** Ada.Streams;
package Ada.Exceptions **is**
 pragma Preelaborate(Exceptions);
 type Exception_Id **is private**;
 pragma Preelaborable_Initialization(Exception_Id);
 Null_Id : **constant** Exception_Id;
 function Exception_Name(Id : Exception_Id) **return** String;
 function Wide_Exception_Name(Id : Exception_Id) **return** Wide_String;
 function Wide_Wide_Exception_Name(Id : Exception_Id)
 return Wide_Wide_String;
- 3/2 {AI95-00362-01} **type** Exception_Occurrence **is limited private**;
 pragma Preelaborable_Initialization(Exception_Occurrence);
 type Exception_Occurrence_Access **is access all** Exception_Occurrence;
 Null_Occurrence : **constant** Exception_Occurrence;
- 4/3 {AI95-00329-01} {AI05-0229-1} **procedure** Raise_Exception(E : **in** Exception_Id;
 Message : **in** String := "")
 with No_Return;
 function Exception_Message(X : Exception_Occurrence) **return** String;
 procedure Reraise_Occurrence(X : **in** Exception_Occurrence);
- 5/2 {AI95-00400-01} **function** Exception_Identity(X : Exception_Occurrence)
 return Exception_Id;
 function Exception_Name(X : Exception_Occurrence) **return** String;
 -- Same as Exception_Name(Exception_Identity(X)).
 function Wide_Exception_Name(X : Exception_Occurrence)
 return Wide_String;
 -- Same as Wide_Exception_Name(Exception_Identity(X)).
 function Wide_Wide_Exception_Name(X : Exception_Occurrence)
 return Wide_Wide_String;
 -- Same as Wide_Wide_Exception_Name(Exception_Identity(X)).
 function Exception_Information(X : Exception_Occurrence) **return** String;
- 6/2 {AI95-00438-01} **procedure** Save_Occurrence(Target : **out** Exception_Occurrence;
 Source : **in** Exception_Occurrence);
 function Save_Occurrence(Source : Exception_Occurrence)
 return Exception_Occurrence_Access;
- 6.1/2 {AI95-00438-01} **procedure** Read_Exception_Occurrence
 (Stream : **not null access** Ada.Streams.Root_Stream_Type'Class;
 Item : **out** Exception_Occurrence);
 procedure Write_Exception_Occurrence
 (Stream : **not null access** Ada.Streams.Root_Stream_Type'Class;
 Item : **in** Exception_Occurrence);
- 6.2/2 {AI95-00438-01} **for** Exception_Occurrence'Read **use** Read_Exception_Occurrence;
 for Exception_Occurrence'Write **use** Write_Exception_Occurrence;

```
{AI95-00438-01} private
... -- not specified by the language
end Ada.Exceptions;
```

Each distinct exception is represented by a distinct value of type `Exception_Id`. `Null_Id` does not represent any exception, and is the default initial value of type `Exception_Id`. Each occurrence of an exception is represented by a value of type `Exception_Occurrence`. `Null_Occurrence` does not represent any exception occurrence, and is the default initial value of type `Exception_Occurrence`.

For a prefix `E` that denotes an exception, the following attribute is defined:

`E'Identity` `E'Identity` returns the unique identity of the exception. The type of this attribute is `Exception_Id`.

Ramification: In a distributed program, the identity is unique across an entire program, not just across a single partition. Exception propagation works properly across RPC's. An exception can be propagated from one partition to another, and then back to the first, where its identity is known.

{AI95-00361-01} `Raise_Exception` raises a new occurrence of the identified exception.

{AI95-00361-01} {AI95-00378-01} {AI05-0043-1} {AI05-0248-1} `Exception_Message` returns the message associated with the given `Exception_Occurrence`. For an occurrence raised by a call to `Raise_Exception`, the message is the `Message` parameter passed to `Raise_Exception`. For the occurrence raised by a `raise_statement` with an *exception_name* and a *string_expression*, the message is the *string_expression*. For the occurrence raised by a `raise_statement` with an *exception_name* but without a *string_expression*, the message is a string giving implementation-defined information about the exception occurrence. For an occurrence originally raised in some other manner (including by the failure of a language-defined check), the message is an unspecified string. In all cases, `Exception_Message` returns a string with lower bound 1.

Implementation defined: The information returned by `Exception_Message`.

Discussion: {AI05-0043-1} There is Implementation Advice about the contents of this string for language-defined checks.

Ramification: Given an exception `E`, the `raise_statement`:

```
raise E;
```

is equivalent to this call to `Raise_Exception`:

```
Raise_Exception(E'Identity, Message => implementation-defined-string);
```

{AI95-00361-01} Similarly, the `raise_statement`:

```
raise E with "some information";
```

is equivalent to this call to `Raise_Exception`:

```
Raise_Exception(E'Identity, Message => "some information");
```

{AI95-00361-01} `Reraise_Occurrence` reraises the specified exception occurrence.

Ramification: The following handler:

```
when others =>
  Cleanup;
  raise;
```

is equivalent to this one:

```
when X : others =>
  Cleanup;
  Reraise_Occurrence(X);
```

`Exception_Identity` returns the identity of the exception of the occurrence.

{AI95-00400-01} The `Wide_Wide_Exception_Name` functions return the full expanded name of the exception, in upper case, starting with a root library unit. For an exception declared immediately within package `Standard`, the `defining_identifier` is returned. The result is implementation defined if the exception is declared within an unnamed `block_statement`.

- 12.a **Ramification:** See the Implementation Permission below.
- 12.b **To be honest:** This name, as well as each prefix of it, does not denote a renaming_declaration.
- 12.c/2 **Implementation defined:** The result of Exceptions.Wide_Wide_Exception_Name for exceptions declared within an unnamed block_statement.
- 12.d **Ramification:** Note that we're talking about the name of the exception, not the name of the occurrence.
- 12.1/2 {AI95-00400-01} The Exception_Name functions (respectively, Wide_Exception_Name) return the same sequence of graphic characters as that defined for Wide_Wide_Exception_Name, if all the graphic characters are defined in Character (respectively, Wide_Character); otherwise, the sequence of characters is implementation defined, but no shorter than that returned by Wide_Wide_Exception_Name for the same value of the argument.
- 12.e/2 **Implementation defined:** The sequence of characters of the value returned by Exceptions.Exception_Name (respectively, Exceptions.Wide_Exception_Name) when some of the graphic characters of Exceptions.Wide_Wide_Exception_Name are not defined in Character (respectively, Wide_Character).
- 12.2/2 {AI95-00378-01} {AI95-00417-01} The string returned by the Exception_Name, Wide_Exception_Name, and Wide_Wide_Exception_Name functions has lower bound 1.
- 13/2 {AI95-00378-01} Exception_Information returns implementation-defined information about the exception occurrence. The returned string has lower bound 1.
- 13.a **Implementation defined:** The information returned by Exception_Information.
- 14/2 {AI95-00241-01} {AI95-00446-01} Reraise_Occurrence has no effect in the case of Null_Occurrence. Raise_Exception and Exception_Name raise Constraint_Error for a Null_Id. Exception_Message, Exception_Name, and Exception_Information raise Constraint_Error for a Null_Occurrence. Exception_Identity applied to Null_Occurrence returns Null_Id.
- 14.a.1/2 **Ramification:** {AI95-00241-01} Null_Occurrence can be tested for by comparing Exception_Identity(Occurrence) to Null_Id.
- 14.a.2/2 **Discussion:** {AI95-00446-01} Raise_Exception was changed so that it always raises an exception and thus can be a No_Return procedure. A similar change was not made for Reraise_Occurrence, as doing so was determined to be a significant incompatibility. It is not unusual to pass an Exception_Occurrence to other code to delay raising it. If there was no exception, passing Null_Occurrence works fine (nothing is raised). Moreover, as there is no test for Null_Occurrence in Ada 95, this is the only way to write such code without using additional flags. Breaking this sort of code is unacceptable.
- 15 The Save_Occurrence procedure copies the Source to the Target. The Save_Occurrence function uses an allocator of type Exception_Occurrence_Access to create a new object, copies the Source to this new object, and returns an access value designating this new object; [the result may be deallocated using an instance of Unchecked_Deallocation.]
- 15.a **Ramification:** It's OK to pass Null_Occurrence to the Save_Occurrence subprograms; they don't raise an exception, but simply save the Null_Occurrence.
- 15.1/2 {AI95-00438-01} Write_Exception_Occurrence writes a representation of an exception occurrence to a stream; Read_Exception_Occurrence reconstructs an exception occurrence from a stream (including one written in a different partition).
- 15.b/2 **Ramification:** This routines are used to define the stream attributes (see 13.13.2) for Exception_Occurrence.
- 15.c/2 The identity of the exception, as well as the Exception_Name and Exception_Message, have to be preserved across partitions.
- 15.d/2 The string returned by Exception_Name or Exception_Message on the result of calling the Read attribute on a given stream has to be the same as the value returned by calling the corresponding function on the exception occurrence that was written into the stream with the Write attribute. The string returned by Exception_Information need not be the same, since it is implementation defined anyway.
- 15.e/2 **Reason:** This is important for supporting writing exception occurrences to external files for post-mortem analysis, as well as propagating exceptions across remote subprogram calls in a distributed system (see E.4).

Paragraph 16 was deleted.

Implementation Permissions

An implementation of `Exception_Name` in a space-constrained environment may return the `defining_`-`identifier` instead of the full expanded name. 17

The string returned by `Exception_Message` may be truncated (to no less than 200 characters) by the `Save_Occurrence` procedure [(not the function)], the `Reraise_Occurrence` procedure, and the re-raise statement. 18

Reason: The reason for allowing truncation is to ease implementations. The reason for choosing the number 200 is that this is the minimum source line length that implementations have to support, and this feature seems vaguely related since it's usually a "one-liner". Note that an implementation is allowed to do this truncation even if it supports arbitrarily long lines. 18.a

Implementation Advice

`Exception_Message` (by default) and `Exception_Information` should produce information useful for debugging. `Exception_Message` should be short (about one line), whereas `Exception_Information` can be long. `Exception_Message` should not include the `Exception_Name`. `Exception_Information` should include both the `Exception_Name` and the `Exception_Message`. 19

Implementation Advice: `Exception_Information` should provide information useful for debugging, and should include the `Exception_Name` and `Exception_Message`. 19.a.1/2

Implementation Advice: `Exception_Message` by default should be short, provide information useful for debugging, and should not include the `Exception_Name`. 19.a.2/2

Reason: It may seem strange to define two subprograms whose semantics is implementation defined. The idea is that a program can print out debugging/error-logging information in a portable way. The program is portable in the sense that it will work in any implementation; it might print out different information, but the presumption is that the information printed out is appropriate for debugging/error analysis on that system. 19.a

Implementation Note: As an example, `Exception_Information` might include information identifying the location where the exception occurred, and, for predefined exceptions, the specific kind of language-defined check that failed. There is an implementation trade-off here, between how much information is represented in an `Exception_Occurrence`, and how much can be passed through a re-raise. 19.b

The string returned should be in a form suitable for printing to an error log file. This means that it might need to contain line-termination control characters with implementation-defined I/O semantics. The string should neither start nor end with a newline. 19.c

If an implementation chooses to provide additional functionality related to exceptions and their occurrences, it should do so by providing one or more children of `Ada.Exceptions`. 19.d

Note that exceptions behave as if declared at library level; there is no "natural scope" for an exception; an exception always exists. Hence, there is no harm in saving an exception occurrence in a data structure, and reraising it later. The reraise has to occur as part of the same program execution, so saving an exception occurrence in a file, reading it back in from a different program execution, and then reraising it is not required to work. This is similar to I/O of access types. Note that it is possible to use RPC to propagate exceptions across partitions. 19.e

Here's one way to implement `Exception_Occurrence` in the private part of the package. Using this method, an implementation need store only the actual number of characters in exception messages. If the user always uses small messages, then exception occurrences can be small. If the user never uses messages, then exception occurrences can be smaller still: 19.f

```

type Exception_Occurrence(Message_Length : Natural := 200) is
  limited record
    Id : Exception_Id;
    Message : String(1..Message_Length);
  end record;
  
```

 19.g

At the point where an exception is raised, an `Exception_Occurrence` can be allocated on the stack with exactly the right amount of space for the message — none for an empty message. This is just like declaring a constrained object of the type: 19.h

```

Temp : Exception_Occurrence(10); -- for a 10-character message
  
```

 19.i

- 19.j After finding the appropriate handler, the stack can be cut back, and the Temp copied to the right place. This is similar to returning an unknown-sized object from a function. It is not necessary to allocate the maximum possible size for every Exception_Occurrence. If, however, the user declares an Exception_Occurrence object, the discriminant will be permanently set to 200. The Save_Occurrence procedure would then truncate the Exception_Message. Thus, nothing is lost until the user tries to save the occurrence. If the user is willing to pay the cost of heap allocation, the Save_Occurrence function can be used instead.
- 19.k Note that any arbitrary-sized implementation-defined Exception_Information can be handled in a similar way. For example, if the Exception_Occurrence includes a stack traceback, a discriminant can control the number of stack frames stored. The traceback would be truncated or entirely deleted by the Save_Occurrence procedure — as the implementation sees fit.
- 19.l If the internal representation involves pointers to data structures that might disappear, it would behoove the implementation to implement it as a controlled type, so that assignment can either copy the data structures or else null out the pointers. Alternatively, if the data structures being pointed at are in a task control block, the implementation could keep a unique sequence number for each task, so it could tell when a task's data structures no longer exist.
- 19.m Using the above method, heap space is never allocated unless the user calls the Save_Occurrence function.
- 19.n An alternative implementation would be to store the message strings on the heap when the exception is raised. (It could be the global heap, or it could be a special heap just for this purpose — it doesn't matter.) This representation would be used only for choice parameters. For normal user-defined exception occurrences, the Save_Occurrence procedure would copy the message string into the occurrence itself, truncating as necessary. Thus, in this implementation, Exception_Occurrence would be implemented as a variant record:
- 19.o
- ```
19.p type Exception_Occurrence_Kind is (Normal, As_Choice_Param);
 type Exception_Occurrence(Kind : Exception_Occurrence_Kind := Normal) is
 limited record
 case Kind is
 when Normal =>
 ... -- space for 200 characters
 when As_Choice_Param =>
 ... -- pointer to heap string
 end case;
 end record;
```
- 19.q Exception\_Occurrences created by the run-time system during exception raising would be As\_Choice\_Param. User-declared ones would be Normal — the user cannot see the discriminant, and so cannot set it to As\_Choice\_Param. The strings in the heap would be freed upon completion of the handler.
- 19.r This alternative implementation corresponds to a heap-based implementation of functions returning unknown-sized results.
- 19.s One possible implementation of Reraise\_Occurrence is as follows:
- ```
19.t    procedure Reraise_Occurrence(X : in Exception_Occurrence) is
    begin
        Raise_Exception(Identity(X), Exception_Message(X));
    end Reraise_Occurrence;
```
- 19.u However, some implementations may wish to retain more information across a re-raise — a stack traceback, for example.
- 19.v **Ramification:** Note that Exception_Occurrence is a definite subtype. Hence, values of type Exception_Occurrence may be written to an error log for later analysis, or may be passed to subprograms for immediate error analysis.
- 19.w/2 *This paragraph was deleted. {AI95-00400-01}*
- Extensions to Ada 83*
- 19.x The Identity attribute of exceptions is new, as is the package Exceptions.
- Inconsistencies With Ada 95*
- 19.y/2 {AI95-00241-01} **Amendment Correction:** Exception_Identity of an Exception_Occurrence now is defined to return Null_Id for Null_Occurrence, rather than raising Constraint_Error. This provides a simple way to test for Null_Occurrence. We expect that programs that need Constraint_Error raised will be very rare; they can be easily fixed by explicitly testing for Null_Id or by using Exception_Name instead.
- 19.z/2 {AI95-00378-01} {AI95-00417-01} **Amendment Correction:** We now define the lower bound of the string returned from [[Wide_]Wide_]Exception_Name, Exception_Message, and Exception_Information. This makes working with the returned string easier, and is consistent with many other string-returning functions in Ada. This is technically an inconsistency; if a program depended on some other lower bound for the string returned from one of these functions, it

could fail when compiled with Ada 2005. Such code is not portable even between Ada 95 implementations, so it should be very rare.

{AI95-00446-01} **Amendment Correction:** Raise_Exception now raises Constraint_Error if passed Null_Id. This means that it always raises an exception, and thus we can apply pragma No_Return to it. We expect that programs that call Raise_Exception with Null_Id will be rare, and programs that do that and expect no exception to be raised will be rarer; such programs can be easily fixed by explicitly testing for Null_Id before calling Raise_Exception. 19.aa/2

Incompatibilities With Ada 95

{AI95-00400-01} {AI95-00438-01} {AI05-0005-1} Functions Wide_Exception_Name and Wide_Wide_Exception_Name, and procedures Read_Exception_Occurrence and Write_Exception_Occurrence are added to Exceptions. If Exceptions is referenced in a use_clause, and an entity *E* with the same defining_identifier as a new entity in Exceptions is defined in a package that is also referenced in a use_clause, the entity *E* may no longer be use-visible, resulting in errors. This should be rare and is easily fixed if it does occur. 19.bb/3

Extensions to Ada 95

{AI95-00362-01} The package Exceptions is preelaborated, and types Exception_Id and Exception_Occurrence have preelaborable initialization, allowing this package to be used in preelaborated units. 19.cc/2

Wording Changes from Ada 95

{AI95-00361-01} The meaning of Exception_Message is reworded to reflect that the string can come from a raise_statement as well as a call of Raise_Exception. 19.dd/2

{AI95-00400-01} Added Wide_Exception_Name and Wide_Wide_Exception_Name because identifiers can now contain characters outside of Latin-1. 19.ee/2

Wording Changes from Ada 2005

{AI05-0043-1} **Correction:** Added explicit wording that the exception message for language-defined checks is unspecified. The old wording appeared inclusive, but it was not. 19.ff/3

11.4.2 Pragmas Assert and Assertion_Policy

{AI95-00286-01} {AI05-0274-1} Pragma Assert is used to assert the truth of a boolean expression at a point within a sequence of declarations or statements. 1/3

{AI05-0274-1} Assert pragmas, subtype predicates (see 3.2.4), preconditions and postconditions (see 6.1.1), and type invariants (see 7.3.2) are collectively referred to as *assertions*; their boolean expressions are referred to as *assertion expressions*. 1.1/3

Glossary entry: A predicate is an assertion that is expected to be True for all objects of a given subtype. 1.a.1/3

Glossary entry: A precondition is an assertion that is expected to be True when a given subprogram is called. 1.a.2/3

Glossary entry: A postcondition is an assertion that is expected to be True when a given subprogram returns normally. 1.a.3/3

Glossary entry: An invariant is an assertion that is expected to be True for all objects of a given private type when viewed from outside the defining package. 1.a.4/3

Glossary entry: An assertion is a boolean expression that appears in any of the following: a pragma Assert, a predicate, a precondition, a postcondition, an invariant, a constraint, or a null exclusion. An assertion is expected to be True at run time at certain specified places. 1.a.5/3

{AI05-0274-1} Pragma Assertion_Policy is used to control whether assertions are to be ignored by the implementation, checked at run time, or handled in some implementation-defined manner. 1.2/3

Syntax

{AI95-00286-01} The form of a pragma Assert is as follows: 2/2

pragma Assert([Check =>] *boolean_expression* [, [Message =>] *string_expression*]); 3/2

A pragma Assert is allowed at the place where a *declarative_item* or a *statement* is allowed. 4/2

5/2 {AI95-00286-01} The form of a pragma Assertion_Policy is as follows:

6/2 **pragma** Assertion_Policy(*policy_identifier*);

6.1/3 {AI05-0290-1} **pragma** Assertion_Policy(
assertion_aspect_mark => *policy_identifier*
 {, *assertion_aspect_mark* => *policy_identifier*});

7/3 {AI05-0290-1} A pragma Assertion_Policy is allowed only immediately within a declarative_part, immediately within a package_specification, or as a configuration pragma.

Name Resolution Rules

8/2 {AI95-00286-01} The expected type for the *boolean_expression* of a pragma Assert is any boolean type. The expected type for the *string_expression* of a pragma Assert is type String.

8.a/2 **Reason:** We allow any boolean type to be like if_statements and other conditionals; we only allow String for the message in order to match raise_statements.

Legality Rules

9/3 {AI95-00286-01} {AI05-0290-1} The *assertion_aspect_mark* of a pragma Assertion_Policy shall be one of Assert, Static_Predicate, Dynamic_Predicate, Pre, Pre'Class, Post, Post'Class, Type_Invariant, Type_Invariant'Class, or some implementation defined *aspect_mark*. The *policy_identifier* shall be either Check, Ignore, or some implementation-defined identifier.

9.a/3 **Implementation defined:** Implementation-defined *policy_identifiers* and *assertion_aspect_marks* allowed in a pragma Assertion_Policy.

Static Semantics

10/3 {AI95-00286-01} {AI05-0290-1} A pragma Assertion_Policy determines for each assertion aspect named in the pragma_argument_associations whether assertions of the given aspect are to be enforced by a run-time check. The *policy_identifier* Check requires that assertion expressions of the given aspect be checked that they evaluate to True at the points specified for the given aspect; the *policy_identifier* Ignore requires that the assertion expression not be evaluated at these points, and the run-time checks not be performed. [Note that for subtype predicate aspects (see 3.2.4), even when the applicable Assertion_Policy is Ignore, the predicate will still be evaluated as part of membership tests and Valid attribute_references, and if static, will still have an effect on loop iteration over the subtype, and the selection of case_statement_alternatives and variants.]

10.1/3 {AI05-0290-1} If no *assertion_aspect_marks* are specified in the pragma, the specified policy applies to all assertion aspects.

10.2/3 {AI05-0290-1} A pragma Assertion_Policy applies to the named assertion aspects in a specific region, and applies to all assertion expressions specified in that region. A pragma Assertion_Policy given in a declarative_part or immediately within a package_specification applies from the place of the pragma to the end of the innermost enclosing declarative region. The region for a pragma Assertion_Policy given as a configuration pragma is the declarative region for the entire compilation unit (or units) to which it applies.

10.3/3 {AI05-0290-1} If a pragma Assertion_Policy applies to a generic_instantiation, then the pragma Assertion_Policy applies to the entire instance.

10.a.1/3 **Ramification:** This means that an Assertion_Policy pragma that occurs in a scope enclosing the declaration of a generic unit but not also enclosing the declaration of a given instance of that generic unit will not apply to assertion expressions occurring within the given instance.

10.4/3 {AI05-0290-1} If multiple Assertion_Policy pragmas apply to a given construct for a given assertion aspect, the assertion policy is determined by the one in the innermost enclosing region of a pragma

Assertion_Policy specifying a policy for the assertion aspect. If no such Assertion_Policy pragma exists, the policy is implementation defined.

Implementation defined: The default assertion policy.	10.a/2
{AI95-00286-01} The following language-defined library package exists:	11/2
<pre>package Ada.Assertions is pragma Pure (Assertions); Assertion_Error : exception; procedure Assert (Check : in Boolean); procedure Assert (Check : in Boolean; Message : in String); end Ada.Assertions;</pre>	12/2 13/2 14/2 15/2
{AI95-00286-01} {AI05-0290-1} A compilation unit containing a check for an assertion (including a pragma Assert) has a semantic dependence on the Assertions library unit.	16/3
<i>This paragraph was deleted.</i> {AI95-00286-01} {AI05-0290-1}	17/3

Dynamic Semantics

{AI95-00286-01} {AI05-0290-1} If performing checks is required by the Assert assertion policy in effect at the place of a pragma Assert, the elaboration of the pragma consists of evaluating the boolean expression, and if the result is False, evaluating the Message argument, if any, and raising the exception Assertions.Assertion_Error, with a message if the Message argument is provided.	18/3
{AI95-00286-01} Calling the procedure Assertions.Assert without a Message parameter is equivalent to:	19/2
<pre>if Check = False then raise Ada.Assertions.Assertion_Error; end if;</pre>	20/2
{AI95-00286-01} Calling the procedure Assertions.Assert with a Message parameter is equivalent to:	21/2
<pre>if Check = False then raise Ada.Assertions.Assertion_Error with Message; end if;</pre>	22/2
{AI95-00286-01} The procedures Assertions.Assert have these effects independently of the assertion policy in effect.	23/2

Bounded (Run-Time) Errors

{AI05-0274-1} It is a bounded error to invoke a potentially blocking operation (see 9.5.1) during the evaluation of an assertion expression associated with a call on, or return from, a protected operation. If the bounded error is detected, Program_Error is raised. If not detected, execution proceeds normally, but if it is invoked within a protected action, it might result in deadlock or a (nested) protected action.	23.1/3
--	--------

Implementation Permissions

{AI95-00286-01} Assertion_Error may be declared by renaming an implementation-defined exception from another package.	24/2
Reason: This permission is intended to allow implementations which had an implementation-defined Assert pragma to continue to use their originally defined exception. Without this permission, such an implementation would be incorrect, as Exception_Name would return the wrong name.	24.a/2
{AI95-00286-01} Implementations may define their own assertion policies.	25/2
{AI05-0274-1} If the result of a function call in an assertion is not needed to determine the value of the assertion expression, an implementation is permitted to omit the function call. [This permission applies even if the function has side effects.]	26/3

- 27/3 {AI05-0274-1} An implementation need not allow the specification of an assertion expression if the evaluation of the expression has a side effect such that an immediate reevaluation of the expression could produce a different value. Similarly, an implementation need not allow the specification of an assertion expression that is checked as part of a call on or return from a callable entity *C*, if the evaluation of the expression has a side effect such that the evaluation of some other assertion expression associated with the same call of (or return from) *C* could produce a different value than it would if the first expression had not been evaluated.
- 27.a/3 **Ramification:** This allows an implementation to reject such assertions. To maximize portability, assertions should not include expressions that contain these sorts of side effects.
- 27.b/3 **Discussion:** The intended effect of the second part of the rule (the part starting with “Similarly”) is that an evaluation of the involved assertion expressions (subtype predicates, type invariants, preconditions and postconditions) in any order yields identical results.
- 27.c/3 The rule is intended to apply to all of the assertion expressions that are evaluated at the start of call (and similarly for the assertion expressions that are evaluated during the return from a call), but not other assertions actually given in the body, nor between the assertions checked at the start and end of the call. Specifically, a side effect that alters a variable in a function called from a precondition expression that changes the result of a postcondition expression of the same subprogram does *not* trigger these rules unless it also changes the value of a reevaluation of the precondition expression.
- NOTES
- 28/2 2 {AI95-00286-01} Normally, the boolean expression in a `pragma Assert` should not call functions that have significant side effects when the result of the expression is True, so that the particular assertion policy in effect will not affect normal operation of the program.

Extensions to Ada 95

- 28.a/2 {AI95-00286-01} Pragma `Assert` and `Assertion_Policy`, and package `Assertions` are new.

Incompatibilities With Ada 2005

- 28.b/3 {AI05-0274-1} There now is an Implementation Permission to reject an assertion expression that calls a function that has a side effect such that an immediate reevaluation of the expression could produce a different value. This means that a `pragma Assert` that works in Ada 2005 might be illegal in Ada 2012 in the unlikely event that the compiler detected such an error. This should be unlikely to occur in practice and it is considered a good thing, as the original expression was tricky and probably was not portable (as order of evaluation is unspecified within an expression). Moreover, no compiler is *required* to reject such expressions, so there is no need for any compiler to change behavior.

Extensions to Ada 2005

- 28.c/3 {AI05-0290-1} `Assertion_Policy` pragmas are now allowed in more places and can specify behavior for individual kinds of assertions.

11.4.3 Example of Exception Handling

Examples

- 1 Exception handling may be used to separate the detection of an error from the response to that error:
- 2/2 {AI95-00433-01} `package File_System is`
 type File_Handle **is limited private**;
 3 File_Not_Found : **exception**;
 procedure Open(F : **in out** File_Handle; Name : String);
 -- raises File_Not_Found if named file does not exist
 4 End_Of_File : **exception**;
 procedure Read(F : **in out** File_Handle; Data : **out** Data_Type);
 -- raises End_Of_File if the file is not open
 5 ...
 end File_System;

```

{AI95-00433-01} package body File_System is
  procedure Open(F : in out File_Handle; Name : String) is
  begin
    if File_Exists(Name) then
      ...
    else
      raise File_Not_Found with "File not found: " & Name & ".";
    end if;
  end Open;

  procedure Read(F : in out File_Handle; Data : out Data_Type) is
  begin
    if F.Current_Position <= F.Last_Position then
      ...
    else
      raise End_Of_File;
    end if;
  end Read;

  ...

end File_System;

with Ada.Text_IO;
with Ada.Exceptions;
with File_System; use File_System;
use Ada;
procedure Main is
begin
  ... -- call operations in File_System
exception
  when End_Of_File =>
    Close(Some_File);
  when Not_Found_Error : File_Not_Found =>
    Text_IO.Put_Line(Exceptions.Exception_Message(Not_Found_Error));
  when The_Error : others =>
    Text_IO.Put_Line("Unknown error:");
    if Verbosity_Desired then
      Text_IO.Put_Line(Exceptions.Exception_Information(The_Error));
    else
      Text_IO.Put_Line(Exceptions.Exception_Name(The_Error));
      Text_IO.Put_Line(Exceptions.Exception_Message(The_Error));
    end if;
    raise;
end Main;

```

In the above example, the `File_System` package contains information about detecting certain exceptional situations, but it does not specify how to handle those situations. Procedure `Main` specifies how to handle them; other clients of `File_System` might have different handlers, even though the exceptional situations arise from the same basic causes.

Wording Changes from Ada 83

{AI05-0299-1} The sections labeled “Exceptions Raised During ...” are subsumed by this subclause, and by parts of Clause 9.

11.5 Suppressing Checks

{AI95-00224-01} *Checking pragmas* give instructions to an implementation on handling language-defined checks. A pragma `Suppress` gives permission to an implementation to omit certain language-defined checks, while a pragma `Unsuppress` revokes the permission to omit checks..

{AI05-0264-1} A *language-defined check* (or simply, a “check”) is one of the situations defined by this International Standard that requires a check to be made at run time to determine whether some condition is true. A check *fails* when the condition being checked is `False`, causing an exception to be raised.

2.a **Discussion:** All such checks are defined under “Dynamic Semantics” in clauses and subclauses throughout the standard.

Syntax

3/2 {AI95-00224-01} The forms of checking pragmas are as follows:

4/2 {AI95-00224-01} **pragma** Suppress(identifier);

4.1/2 {AI95-00224-01} **pragma** Unsuppress(identifier);

5/2 {AI95-00224-01} A checking pragma is allowed only immediately within a `declarative_part`, immediately within a `package_specification`, or as a configuration pragma.

Legality Rules

6/2 {AI95-00224-01} The identifier shall be the name of a check.

7/2 *This paragraph was deleted.* {AI95-00224-01}

Static Semantics

7.1/2 {AI95-00224-01} A checking pragma applies to the named check in a specific region, and applies to all entities in that region. A checking pragma given in a `declarative_part` or immediately within a `package_specification` applies from the place of the pragma to the end of the innermost enclosing declarative region. The region for a checking pragma given as a configuration pragma is the declarative region for the entire compilation unit (or units) to which it applies.

7.2/3 {AI95-00224-01} {AI05-0229-1} {AI05-0290-1} If a checking pragma applies to a `generic_instantiation`, then the checking pragma also applies to the entire instance.

7.a/3 **Ramification:** {AI05-0290-1} This means that a Suppress pragma that occurs in a scope enclosing the declaration of a generic unit but not also enclosing the declaration of a given instance of that generic unit will not apply to constructs within the given instance.

8/2 {AI95-00224-01} A **pragma** Suppress gives permission to an implementation to omit the named check (or every check in the case of `All_Checks`) for any entities to which it applies. If permission has been given to suppress a given check, the check is said to be *suppressed*.

8.a **Ramification:** A check is suppressed even if the implementation chooses not to actually generate better code. This allows the implementation to raise `Program_Error`, for example, if the erroneousousness is detected.

8.1/2 {AI95-00224-01} A **pragma** Unsuppress revokes the permission to omit the named check (or every check in the case of `All_Checks`) given by any **pragma** Suppress that applies at the point of the **pragma** Unsuppress. The permission is revoked for the region to which the **pragma** Unsuppress applies. If there is no such permission at the point of a **pragma** Unsuppress, then the **pragma** has no effect. A later **pragma** Suppress can renew the permission.

9 The following are the language-defined checks:

- 10 • [The following checks correspond to situations in which the exception `Constraint_Error` is raised upon failure.]

11/2 {8652/0036} {AI95-00176-01} {AI95-00231-01} `Access_Check`

[When evaluating a dereference (explicit or implicit), check that the value of the name is not **null**. When converting to a subtype that excludes null, check that the converted value is not **null**.]

12 `Discriminant_Check`

[Check that the discriminants of a composite value have the values imposed by a discriminant constraint. Also, when accessing a record component, check that it exists for the current discriminant values.]

<code>{AI95-00434-01}</code> Division_Check	13/2
[Check that the second operand is not zero for the operations <code>/</code> , <code>rem</code> and <code>mod</code> .]	
Index_Check	14
[Check that the bounds of an array value are equal to the corresponding bounds of an index constraint. Also, when accessing a component of an array object, check for each dimension that the given index value belongs to the range defined by the bounds of the array object. Also, when accessing a slice of an array object, check that the given discrete range is compatible with the range defined by the bounds of the array object.]	
Length_Check	15
[Check that two arrays have matching components, in the case of array subtype conversions, and logical operators for arrays of boolean components.]	
Overflow_Check	16
[Check that a scalar value is within the base range of its type, in cases where the implementation chooses to raise an exception instead of returning the correct mathematical result.]	
Range_Check	17
[Check that a scalar value satisfies a range constraint. Also, for the elaboration of a <code>subtype_indication</code> , check that the <code>constraint</code> (if present) is compatible with the subtype denoted by the <code>subtype_mark</code> . Also, for an <code>aggregate</code> , check that an index or discriminant value belongs to the corresponding subtype. Also, check that when the result of an operation yields an array, the value of each component belongs to the component subtype.]	
Tag_Check	18
[Check that operand tags in a dispatching call are all equal. Check for the correct tag on tagged type conversions, for an <code>assignment_statement</code> , and when returning a tagged limited object from a function.]	
• [The following checks correspond to situations in which the exception <code>Program_Error</code> is raised upon failure.]	19
<code>{AI95-00280}</code> Accessibility_Check	19.1/2
[Check the accessibility level of an entity or view.]	
<code>{AI95-00280}</code> Allocation_Check	19.2/2
[For an <code>allocator</code> , check that the master of any tasks to be created by the <code>allocator</code> is not yet completed or some dependents have not yet terminated, and that the finalization of the collection has not started.]	
Elaboration_Check	20
[When a subprogram or protected entry is called, a task activation is accomplished, or a generic instantiation is elaborated, check that the body of the corresponding unit has already been elaborated.]	
<i>This paragraph was deleted. {AI95-00280}</i>	21/2
• [The following check corresponds to situations in which the exception <code>Storage_Error</code> is raised upon failure.]	22
Storage_Check	23
[Check that evaluation of an <code>allocator</code> does not require more space than is available for a storage pool. Check that the space available for a task or subprogram has not been exceeded.]	
Reason: We considered splitting this out into three categories: <code>Pool_Check</code> (for <code>allocators</code>), <code>Stack_Check</code> (for stack usage), and <code>Heap_Check</code> (for implicit use of the heap — use of the heap other than through an <code>allocator</code>).	23.a

Storage_Check would then represent the union of these three. However, there seems to be no compelling reason to do this, given that it is not feasible to split Storage_Error.

- 24 • [The following check corresponds to all situations in which any predefined exception is raised.]
- 25/3 {AI05-0290-1} All_Checks
 Represents the union of all checks; suppressing All_Checks suppresses all checks other than those associated with assertions. In addition, an implementation is allowed (but not required) to behave as if a pragma Assertion_Policy(Ignore) applies to any region to which pragma Suppress(All_Checks) applies.
- 25.a **Ramification:** All_Checks includes both language-defined and implementation-defined checks.
- 25.b/3 **To be honest:** {AI05-0005-1} There are additional checks defined in various Specialized Needs Annexes that are not listed here. Nevertheless, they are included in All_Checks and named in a Suppress pragma on implementations that support the relevant annex. Look up “check, language-defined” in the index to find the complete list.
- 25.c/3 **Discussion:** {AI05-0290-1} We don't want to say that assertions are suppressed, because we don't want the potential failure of an assertion to cause erroneous execution (see below). Thus they are excluded from the suppression part of the above rule and then handled with an implicit Ignore policy.

Erroneous Execution

- 26 If a given check has been suppressed, and the corresponding error situation occurs, the execution of the program is erroneous.

Implementation Permissions

- 27/2 {AI95-00224-01} An implementation is allowed to place restrictions on checking pragmas, subject only to the requirement that pragma Unsuppress shall allow any check names supported by pragma Suppress. An implementation is allowed to add additional check names, with implementation-defined semantics. When Overflow_Check has been suppressed, an implementation may also suppress an unspecified subset of the Range_Checks.
- 27.a/2 *This paragraph was deleted.* {AI95-00224-01}
- 27.b **Implementation defined:** Implementation-defined check names.
- 27.c **Discussion:** For Overflow_Check, the intention is that the implementation will suppress any Range_Checks that are implemented in the same manner as Overflow_Checks (unless they are free).
- 27.1/2 {AI95-00224-01} An implementation may support an additional parameter on pragma Unsuppress similar to the one allowed for pragma Suppress (see J.10). The meaning of such a parameter is implementation-defined.
- 27.c.1/2 **Implementation defined:** Existence and meaning of second parameter of pragma Unsuppress.

Implementation Advice

- 28 The implementation should minimize the code executed for checks that have been suppressed.
- 28.a.1/2 **Implementation Advice:** Code executed for checks that have been suppressed should be minimized.
- 28.a **Implementation Note:** However, if a given check comes for free (for example, the hardware automatically performs the check in parallel with doing useful work) or nearly free (for example, the check is a tiny portion of an expensive run-time system call), the implementation should not bother to suppress the check. Similarly, if the implementation detects the failure at compile time and provides a warning message, there is no need to actually suppress the check.

NOTES

- 29 3 There is no guarantee that a suppressed check is actually removed; hence a pragma Suppress should be used only for efficiency reasons.
- 29.1/2 4 {AI95-00224-01} It is possible to give both a pragma Suppress and Unsuppress for the same check immediately within the same declarative_part. In that case, the last pragma given determines whether or not the check is suppressed. Similarly, it is possible to resuppress a check which has been unsuppressed by giving a pragma Suppress in an inner declarative region.

Examples

- {AI95-00224-01}* *Examples of suppressing and unsuppressing checks:* 30/2
- ```
{AI95-00224-01} pragma Suppress (Index_Check) ; 31/2
pragma Unsuppress (Overflow_Check) ;
```

*Extensions to Ada 83*

- A pragma Suppress is allowed as a configuration pragma. A pragma Suppress without a name is allowed in a package\_specification. 31.a
- Additional check names are added. We allow implementations to define their own checks. 31.b

*Wording Changes from Ada 83*

- We define the checks in a distributed manner. Therefore, the long list of what checks apply to what is merely a NOTE. 31.c
- We have removed the detailed rules about what is allowed in a pragma Suppress, and allow implementations to invent their own. The RM83 rules weren't quite right, and such a change is necessary anyway in the presence of implementation-defined checks. 31.d
- We make it clear that the difference between a Range\_Check and an Overflow\_Check is fuzzy. This was true in Ada 83, given RM83-11.6, but it was not clear. We considered removing Overflow\_Check from the language or making it obsolescent, just as we did for Numeric\_Error. However, we kept it for upward compatibility, and because it may be useful on machines where range checking costs more than overflow checking, but overflow checking still costs something. Different compilers will suppress different checks when asked to suppress Overflow\_Check — the nonuniformity in this case is not harmful, and removing it would have a serious impact on optimizers. 31.e
- Under Access\_Check, dereferences cover the cases of selected\_component, indexed\_component, slice, and attribute that are listed in RM83, as well as the new explicit\_dereference, which was included in selected\_component in RM83. 31.f

*Extensions to Ada 95*

- {AI95-00224-01}* Pragma Unsuppress is new. 31.g/2
- {AI95-00280-01}* Allocation\_Check was added to support suppressing the new check on allocators (see 4.8). 31.h/2

*Wording Changes from Ada 95*

- {8652/0036}* *{AI95-00176-01}* *{AI95-00224-01}* The description of Access\_Check was corrected by the Corrigendum to include the discriminant case. This change was then replaced by the more general notion of checking conversions to subtypes that exclude null in Ada 2005. 31.i/2
- {AI95-00224-01}* The On parameter of pragma Suppress was moved to Annex J (see J.10). This feature's effect is inherently nonportable, depending on the implementation's model of computation. Compiler surveys demonstrated this, showing that implementations vary widely in the interpretation of these parameters, even on the same target. While this is relatively harmless for Suppress (which is never required to do anything), it would be a significant problem for Unsuppress (we want the checks to be made for all implementations). By moving it, we avoid needing to define the meaning of Unsuppress with an On parameter. 31.j/2
- {AI95-00280-01}* The order of the Program\_Error checks was corrected to be alphabetical. 31.k/2

*Wording Changes from Ada 2005*

- {AI05-0290-1}* The effect of a checking pragma no longer applies inside an inlined subprogram body. While this could change the behavior of a program that depends on a check being suppressed in an inlined body, such a program is erroneous and thus no behavior can be depended upon anyway. It's also likely to be very rare. We make this change so that inlining has no effect on the meaning of the subprogram body (since inlining is never requiring, this is necessary in order to be able to reason about the body), and so that assertion policies and suppress work the same way for inlining. 31.l/3

## 11.6 Exceptions and Optimization

- {AI05-0299-1}* [ This subclause gives permission to the implementation to perform certain “optimizations” that do not necessarily preserve the canonical semantics.] 1/3

## Dynamic Semantics

- 2/3 {AI05-0299-1} The rest of this International Standard (outside this subclause) defines the *canonical semantics* of the language. [The canonical semantics of a given (legal) program determines a set of possible external effects that can result from the execution of the program with given inputs.]
- 2.a **Ramification:** Note that the canonical semantics is a set of possible behaviors, since some reordering, parallelism, and nondeterminism is allowed by the canonical semantics.
- 2.b/3 **Discussion:** {AI05-0299-1} The following parts of the canonical semantics are of particular interest to the reader of this subclause:
- 2.c • Behavior in the presence of abnormal objects and objects with invalid representations (see 13.9.1).
  - 2.d • Various actions that are defined to occur in an arbitrary order.
  - 2.e/3 • {AI05-0299-1} Behavior in the presence of a misuse of `Unchecked_Deallocation`, `Unchecked_Access`, or imported or exported entity (see Clause 13).
- 3/3 {AI05-0299-1} [As explained in 1.1.3, “Conformity of an Implementation with the Standard”, the external effect of a program is defined in terms of its interactions with its external environment. Hence, the implementation can perform any internal actions whatsoever, in any order or in parallel, so long as the external effect of the execution of the program is one that is allowed by the canonical semantics, or by the rules of this subclause.]
- 3.a **Ramification:** Note that an optimization can change the external effect of the program, so long as the changed external effect is an external effect that is allowed by the semantics. Note that the canonical semantics of an erroneous execution allows any external effect whatsoever. Hence, if the implementation can prove that program execution will be erroneous in certain circumstances, there need not be any constraints on the machine code executed in those circumstances.

## Implementation Permissions

- 4 The following additional permissions are granted to the implementation:
- 5 • An implementation need not always raise an exception when a language-defined check fails. Instead, the operation that failed the check can simply yield an *undefined result*. The exception need be raised by the implementation only if, in the absence of raising it, the value of this undefined result would have some effect on the external interactions of the program. In determining this, the implementation shall not presume that an undefined result has a value that belongs to its subtype, nor even to the base range of its type, if scalar. [Having removed the raise of the exception, the canonical semantics will in general allow the implementation to omit the code for the check, and some or all of the operation itself.]
- 5.a **Ramification:** Even without this permission, an implementation can always remove a check if it cannot possibly fail.
- 5.b **Reason:** We express the permission in terms of removing the raise, rather than the operation or the check, as it minimizes the disturbance to the canonical semantics (thereby simplifying reasoning). By allowing the implementation to omit the raise, it thereby does not need to “look” at what happens in the exception handler to decide whether the optimization is allowed.
- 5.c **Discussion:** The implementation can also omit checks if they cannot possibly fail, or if they could only fail in erroneous executions. This follows from the canonical semantics.
- 5.d **Implementation Note:** This permission is intended to allow normal “dead code removal” optimizations, even if some of the removed code might have failed some language-defined check. However, one may not eliminate the raise of an exception if subsequent code presumes in some way that the check succeeded. For example:
- 5.e
- ```

    if X * Y > Integer'Last then
        Put_Line("X * Y overflowed");
    end if;
exception
    when others =>
        Put_Line("X * Y overflowed");

```
- 5.e.1 If `X*Y` does overflow, you may not remove the raise of the exception if the code that does the comparison against `Integer'Last` presumes that it is comparing it with an in-range `Integer` value, and hence always yields `False`.
- 5.f As another example where a raise may not be eliminated:

```

subtype Str10 is String(1..10);
type P10 is access Str10;
X : P10 := null;
begin
  if X.all'Last = 10 then
    Put_Line("Oops");
  end if;

```

5.g

In the above code, it would be wrong to eliminate the raise of `Constraint_Error` on the "X.all" (since X is null), if the code to evaluate 'Last always yields 10 by presuming that X.all belongs to the subtype Str10, without even "looking." 5.g.1

- *{AI05-0229-1}* If an exception is raised due to the failure of a language-defined check, then upon reaching the corresponding `exception_handler` (or the termination of the task, if none), the external interactions that have occurred need reflect only that the exception was raised somewhere within the execution of the `sequence_of_statements` with the handler (or the `task_body`), possibly earlier (or later if the interactions are independent of the result of the checked operation) than that defined by the canonical semantics, but not within the execution of some abort-deferred operation or *independent* subprogram that does not dynamically enclose the execution of the construct whose check failed. An independent subprogram is one that is defined outside the library unit containing the construct whose check failed, and for which the `Inline` aspect is `False`. Any assignment that occurred outside of such abort-deferred operations or independent subprograms can be disrupted by the raising of the exception, causing the object or its parts to become abnormal, and certain subsequent uses of the object to be erroneous, as explained in 13.9.1. 6/3

Reason: We allow such variables to become abnormal so that assignments (other than to atomic variables) can be disrupted due to “imprecise” exceptions or instruction scheduling, and so that assignments can be reordered so long as the correct results are produced in the end if no language-defined checks fail. 6.a

Ramification: If a check fails, no result dependent on the check may be incorporated in an external interaction. In other words, there is no permission to output meaningless results due to postponing a check. 6.b

Discussion: We believe it is important to state the extra permission to reorder actions in terms of what the programmer can expect at run time, rather than in terms of what the implementation can assume, or what transformations the implementation can perform. Otherwise, how can the programmer write reliable programs? 6.c

{AI05-0299-1} This subclause has two conflicting goals: to allow as much optimization as possible, and to make program execution as predictable as possible (to ease the writing of reliable programs). The rules given above represent a compromise. 6.d/3

Consider the two extremes: 6.e

{AI05-0299-1} The extreme conservative rule would be to delete this subclause entirely. The semantics of Ada would be the canonical semantics. This achieves the best predictability. It sounds like a disaster from the efficiency point of view, but in practice, implementations would provide modes in which less predictability but more efficiency would be achieved. Such a mode could even be the out-of-the-box mode. In practice, implementers would provide a compromise based on their customer's needs. Therefore, we view this as one viable alternative. 6.f/3

The extreme liberal rule would be “the language does not specify the execution of a program once a language-defined check has failed; such execution can be unpredictable.” This achieves the best efficiency. It sounds like a disaster from the predictability point of view, but in practice it might not be so bad. A user would have to assume that exception handlers for exceptions raised by language-defined checks are not portable. They would have to isolate such code (like all nonportable code), and would have to find out, for each implementation of interest, what behaviors can be expected. In practice, implementations would tend to avoid going so far as to punish their customers too much in terms of predictability. 6.g

{AI05-0299-1} The most important thing about this subclause is that users understand what they can expect at run time, and implementers understand what optimizations are allowed. Any solution that makes this subclause contain rules that can interpreted in more than one way is unacceptable. 6.h/3

We have chosen a compromise between the extreme conservative and extreme liberal rules. The current rule essentially allows arbitrary optimizations within a library unit and inlined subprograms reachable from it, but disallow semantics-disrupting optimizations across library units in the absence of inlined subprograms. This allows a library unit to be debugged, and then reused with some confidence that the abstraction it manages cannot be broken by bugs outside the library unit. 6.i

NOTES

5 *{AI05-0299-1}* The permissions granted by this subclause can have an effect on the semantics of a program only if the program fails a language-defined check. 7/3

Wording Changes from Ada 83

- 7.a RM83-11.6 was unclear. It has been completely rewritten here; we hope this version is clearer. Here's what happened to each paragraph of RM83-11.6:
- 7.b
- Paragraphs 1 and 2 contain no semantics; they are merely pointing out that anything goes if the canonical semantics is preserved. We have similar introductory paragraphs, but we have tried to clarify that these are not granting any “extra” permission beyond what the rest of the document allows.
- 7.c
- Paragraphs 3 and 4 are reflected in the “extra permission to reorder actions”. Note that this permission now allows the reordering of assignments in many cases.
- 7.d
- Paragraph 5 is moved to 4.5, “Operators and Expression Evaluation”, where operator association is discussed. Hence, this is no longer an “extra permission” but is part of the canonical semantics.
- 7.e
- Paragraph 6 now follows from the general permission to store out-of-range values for unconstrained subtypes. Note that the parameters and results of all the predefined operators of a type are of the unconstrained subtype of the type.
- 7.f
- Paragraph 7 is reflected in the “extra permission to avoid raising exceptions”.
- 7.g/3 {AI05-0299-1} We moved subclause 11.5, “Suppressing Checks” from after 11.6 to before 11.6, in order to preserve the famous number “11.6” (given the changes to earlier subclauses in Clause 11).

12 Generic Units

A *generic unit* is a program unit that is either a generic subprogram or a generic package. A generic unit is a *template*[, which can be parameterized, and from which corresponding (nongeneric) subprograms or packages can be obtained]. The resulting program units are said to be *instances* of the original generic unit. 1

Glossary entry: A generic unit is a template for a (nongeneric) program unit; the template can be parameterized by objects, types, subprograms, and packages. An instance of a generic unit is created by a `generic_instantiation`. The rules of the language are enforced when a generic unit is compiled, using a generic contract model; additional checks are performed upon instantiation to verify the contract is met. That is, the declaration of a generic unit represents a contract between the body of the generic and instances of the generic. Generic units can be used to perform the role that macros sometimes play in other languages. 1.a

[A generic unit is declared by a `generic_declaration`. This form of declaration has a `generic_formal_part` declaring any generic formal parameters. An instance of a generic unit is obtained as the result of a `generic_instantiation` with appropriate generic actual parameters for the generic formal parameters. An instance of a generic subprogram is a subprogram. An instance of a generic package is a package. 2

Generic units are templates. As templates they do not have the properties that are specific to their nongeneric counterparts. For example, a generic subprogram can be instantiated but it cannot be called. In contrast, an instance of a generic subprogram is a (nongeneric) subprogram; hence, this instance can be called but it cannot be used to produce further instances.] 3

12.1 Generic Declarations

[A `generic_declaration` declares a generic unit, which is either a generic subprogram or a generic package. A `generic_declaration` includes a `generic_formal_part` declaring any generic formal parameters. A generic formal parameter can be an object; alternatively (unlike a parameter of a subprogram), it can be a type, a subprogram, or a package.] 1

Syntax

```
generic_declaration ::= generic_subprogram_declaration | generic_package_declaration 2
{AI05-0183-1} generic_subprogram_declaration ::= 3/3
    generic_formal_part subprogram_specification
    [aspect_specification];
generic_package_declaration ::= 4
    generic_formal_part package_specification;
```

Ramification: {AI05-0183-1} No syntax change is needed here to allow an `aspect_specification`; a generic package can have an `aspect_specification` because a `package_specification` allows an `aspect_specification`. 4.a/3

```
generic_formal_part ::= generic {generic_formal_parameter_declaration | use_clause} 5
generic_formal_parameter_declaration ::= 6
    formal_object_declaration
    | formal_type_declaration
    | formal_subprogram_declaration
    | formal_package_declaration
```

The only form of `subtype_indication` allowed within a `generic_formal_part` is a `subtype_mark` [(that is, the `subtype_indication` shall not include an explicit constraint)]. The defining name of a generic subprogram shall be an identifier [(not an `operator_symbol`)]. 7

- 7.a **Reason:** The reason for forbidding constraints in `subtype_indications` is that it simplifies the elaboration of `generic_declarations` (since there is nothing to evaluate), and that it simplifies the matching rules, and makes them more checkable at compile time.

Static Semantics

- 8/2 {AI95-00434-01} A `generic_declaration` declares a generic unit — a generic package, generic procedure, or generic function, as appropriate.
- 9 An entity is a *generic formal* entity if it is declared by a `generic_formal_parameter_declaration`. “Generic formal,” or simply “formal,” is used as a prefix in referring to objects, subtypes (and types), functions, procedures and packages, that are generic formal entities, as well as to their respective declarations. [Examples: “generic formal procedure” or a “formal integer type declaration.”]

Dynamic Semantics

- 10 The elaboration of a `generic_declaration` has no effect.

NOTES

- 11 1 Outside a generic unit a name that denotes the `generic_declaration` denotes the generic unit. In contrast, within the declarative region of the generic unit, a name that denotes the `generic_declaration` denotes the current instance.
- 11.a **Proof:** This is stated officially as part of the “current instance” rule in 8.6, “The Context of Overload Resolution”. See also 12.3, “Generic Instantiation”.
- 12 2 Within a generic `subprogram_body`, the name of this program unit acts as the name of a subprogram. Hence this name can be overloaded, and it can appear in a recursive call of the current instance. For the same reason, this name cannot appear after the reserved word `new` in a (recursive) `generic_instantiation`.
- 13 3 A `default_expression` or `default_name` appearing in a `generic_formal_part` is not evaluated during elaboration of the `generic_formal_part`; instead, it is evaluated when used. (The usual visibility rules apply to any name used in a default: the denoted declaration therefore has to be visible at the place of the expression.)

Examples

14 *Examples of generic formal parts:*

```

15 generic      -- parameterless
16 generic
   Size : Natural;  -- formal object
17 generic
   Length : Integer := 200;          -- formal object with a default expression
18   Area  : Integer := Length*Length; -- formal object with a default expression
19 generic
   type Item is private;           -- formal type
   type Index is (<>);             -- formal type
   type Row is array(Index range <>) of Item; -- formal type
   with function "<"(X, Y : Item) return Boolean; -- formal subprogram

```

20 *Examples of generic declarations declaring generic subprograms Exchange and Squaring:*

```

21 generic
   type Elem is private;
   procedure Exchange(U, V : in out Elem);
22 generic
   type Item is private;
   with function "*" (U, V : Item) return Item is <>;
   function Squaring(X : Item) return Item;

```

Example of a generic declaration declaring a generic package:

```

generic
  type Item is private;
  type Vector is array (Positive range <>) of Item;
  with function Sum(X, Y : Item) return Item;
package On_Vectors is
  function Sum (A, B : Vector) return Vector;
  function Sigma(A : Vector) return Item;
  Length_Error : exception;
end On_Vectors;

```

23
24

Extensions to Ada 83

The syntax rule for `generic_formal_parameter_declaration` is modified to allow the reserved words **tagged** and **abstract**, to allow formal derived types, and to allow formal packages. 24.a

`Use_clauses` are allowed in `generic_formal_parts`. This is necessary in order to allow a `use_clause` within a formal part to provide direct visibility of declarations within a generic formal package. 24.b

Wording Changes from Ada 83

{AI05-0299-1} The syntax for `generic_formal_parameter_declaration` and `formal_type_definition` is split up into more named categories. The rules for these categories are moved to the appropriate subclauses. The names of the categories are changed to be more intuitive and uniform. For example, we changed `generic_parameter_declaration` to `generic_formal_parameter_declaration`, because the thing it declares is a generic formal, not a generic. In the others, we abbreviate “generic_formal” to just “formal”. We can't do that for `generic_formal_parameter_declaration`, because of confusion with normal formal parameters of subprograms. 24.c/3

Extensions to Ada 2005

{AI05-0183-1} An optional `aspect_specification` can be used in a `generic_subprogram_declaration` (as well as a `generic_package_declaration`). This is described in 13.1.1. 24.d/3

12.2 Generic Bodies

The body of a generic unit (a *generic body*) [is a template for the instance bodies. The syntax of a generic body is identical to that of a nongeneric body]. 1

Ramification: We also use terms like “generic function body” and “nongeneric package body.” 1.a

Dynamic Semantics

The elaboration of a generic body has no other effect than to establish that the generic unit can from then on be instantiated without failing the `Elaboration_Check`. If the generic body is a child of a generic package, then its elaboration establishes that each corresponding declaration nested in an instance of the parent (see 10.1.1) can from then on be instantiated without failing the `Elaboration_Check`. 2

NOTES

4 The syntax of generic subprograms implies that a generic subprogram body is always the completion of a declaration. 3

Examples

Example of a generic procedure body:

```

procedure Exchange(U, V : in out Elem) is -- see 12.1
  T : Elem; -- the generic formal type
begin
  T := U;
  U := V;
  V := T;
end Exchange;

```

4
5

Example of a generic function body:

```

6  function Squaring(X : Item) return Item is -- see 12.1
7  begin
    return X*X; -- the formal operator "*"
    end Squaring;
```

Example of a generic package body:

```

8  package body On_Vectors is -- see 12.1
9
10     function Sum(A, B : Vector) return Vector is
        Result : Vector(A'Range); -- the formal type Vector
        Bias   : constant Integer := B'First - A'First;
    begin
        if A'Length /= B'Length then
            raise Length_Error;
        end if;
11     for N in A'Range loop
        Result(N) := Sum(A(N), B(N + Bias)); -- the formal function Sum
        end loop;
        return Result;
    end Sum;
12
    function Sigma(A : Vector) return Item is
        Total : Item := A(A'First); -- the formal type Item
    begin
        for N in A'First + 1 .. A'Last loop
            Total := Sum(Total, A(N)); -- the formal function Sum
        end loop;
        return Total;
    end Sigma;
    end On_Vectors;
```

12.3 Generic Instantiation

1 [An instance of a generic unit is declared by a `generic_instantiation`.]

Language Design Principles

1.a/3 {AI05-0299-1} The legality of an instance should be determinable without looking at the generic body. Likewise, the legality of a generic body should be determinable without looking at any instances. Thus, the `generic_declaration` forms a contract between the body and the instances; if each obeys the rules with respect to the `generic_declaration`, then no legality problems will arise. This is really a special case of the “legality determinable via semantic dependences” Language Design Principle (see Clause 10), given that a `generic_instantiation` does not depend semantically upon the generic body, nor vice-versa.

1.b Run-time issues are another story. For example, whether parameter passing is by copy or by reference is determined in part by the properties of the generic actuals, and thus cannot be determined at compile time of the generic body. Similarly, the contract model does not apply to Post-Compilation Rules.

Syntax

<pre> {AI95-00218-03} {AI05-0183-1} generic_instantiation ::= package defining_program_unit_name is new generic_package_name [generic_actual_part] [aspect_specification]; [overriding_indicator] procedure defining_program_unit_name is new generic_procedure_name [generic_actual_part] [aspect_specification]; [overriding_indicator] function defining_designator is new generic_function_name [generic_actual_part] [aspect_specification]; generic_actual_part ::= (generic_association {, generic_association}) generic_association ::= [generic_formal_parameter_selector_name =>] explicit_generic_actual_parameter explicit_generic_actual_parameter ::= expression variable_name subprogram_name entry_name subtype_mark package_instance_name A generic_association is <i>named</i> or <i>positional</i> according to whether or not the <i>generic_formal_</i>- <i>parameter_selector_name</i> is specified. Any positional associations shall precede any named associations.</pre>	<p>2/3</p> <p>3</p> <p>4</p> <p>5</p> <p>6</p>
---	--

{AI05-0004-1} The *generic actual parameter* is either the *explicit_generic_actual_parameter* given in a *generic_association* for each formal, or the corresponding *default_expression* or *default_name* if no *generic_association* is given for the formal. When the meaning is clear from context, the term “generic actual,” or simply “actual,” is used as a synonym for “generic actual parameter” and also for the view denoted by one, or the value of one.

Legality Rules

<p>In a <i>generic_instantiation</i> for a particular kind of program unit [(package, procedure, or function)], the name shall denote a generic unit of the corresponding kind [(generic package, generic procedure, or generic function, respectively)].</p>	<p>8</p>
<p>{AI05-0118-1} The <i>generic_formal_parameter_selector_name</i> of a named <i>generic_association</i> shall denote a <i>generic_formal_parameter_declaration</i> of the generic unit being instantiated. If two or more formal subprograms have the same defining name, then named associations are not allowed for the corresponding actuals.</p>	<p>9/3</p>
<p>{AI05-0118-1} The <i>generic_formal_parameter_declaration</i> for a positional <i>generic_association</i> is the parameter with the corresponding position in the <i>generic_formal_part</i> of the generic unit being instantiated.</p>	<p>9.1/3</p>
<p>A <i>generic_instantiation</i> shall contain at most one <i>generic_association</i> for each formal. Each formal without an association shall have a <i>default_expression</i> or <i>subprogram_default</i>.</p>	<p>10</p>
<p>In a generic unit Legality Rules are enforced at compile time of the <i>generic_declaration</i> and generic body, given the properties of the formals. In the visible part and formal part of an instance, Legality Rules are enforced at compile time of the <i>generic_instantiation</i>, given the properties of the actuals. In other parts of an instance, Legality Rules are not enforced; this rule does not apply when a given rule explicitly specifies otherwise.</p>	<p>11</p>

- 11.a/2 **Reason:** *{AI95-00114-01}* Since rules are checked using the properties of the formals, and since these properties do not always carry over to the actuals, we need to check the rules again in the visible part of the instance. For example, only if a tagged type is limited may an extension of it have limited components in the `record_extension_part`. A formal tagged limited type is limited, but the actual might be nonlimited. Hence any rule that requires a tagged type to be limited runs into this problem. Such rules are rare; in most cases, the rules for matching of formals and actuals guarantee that if the rule is obeyed in the generic unit, then it has to be obeyed in the instance.
- 11.a.1/3 *{AI05-0005-1}* Ada 2012 addendum: Such Legality Rules are not as rare as the authors of Ada 95 hoped; there are more than 30 of them known at this point. They are indexed under "generic contract issue" and are associated with the boilerplate "In addition to the places where Legality Rules normally apply...". Indeed, there is only one known rule where rechecking in the specification is needed and where rechecking in the private part is *not* wanted (it is in 3.4, but even it needs rechecking when tagged types are involved).
- 11.b **Ramification:** The “properties” of the formals are determined without knowing anything about the actuals:
- 11.c/1
- *{8652/0095}* *{AI95-00034-01}* A formal derived subtype is constrained if and only if the ancestor subtype is constrained. A formal array type is constrained if and only if the declarations say so. A formal private type is constrained if it does not have a discriminant part. Other formal subtypes are unconstrained, even though they might be constrained in an instance.
- 11.d
- A formal subtype can be indefinite, even though the copy might be definite in an instance.
- 11.e
- A formal object of mode **in** is not a static constant; in an instance, the copy is static if the actual is.
- 11.f
- A formal subtype is not static, even though the actual might be.
- 11.g
- Formal types are specific, even though the actual can be class-wide.
- 11.h
- The subtype of a formal object of mode **in out** is not static. (This covers the case of AI83-00878.)
- 11.i
- The subtype of a formal parameter of a formal subprogram does not provide an applicable index constraint.
- 11.j/3
- *{AI05-0239-1}* The profile of a formal subprogram is not subtype conformant with any other profile.
- 11.k
- A generic formal function is not static.
- 11.l **Ramification:** The exceptions to the above rule about when legality rules are enforced fall into these categories:
- 11.m
- Some rules are checked in the generic declaration, and then again in both the visible and private parts of the instance:
 - 11.n
 - 11.o
 - 11.p/3
 - 11.q
 - 11.r
- 11.r.1/2 *{AI95-00402-01}* The corrections made by the Corrigendum added a number of such rules, and the Amendment added many more. There doesn't seem to be much value in repeating all of these rules here (as of this writing, there are roughly 33 such rules). As noted below, all such rules are indexed in the AARM.
- 11.s
- For the accessibility rules, the formals have nothing to say about the property in question. Like the above rules, these rules are checked in the generic declaration, and then again in both the visible and private parts of the instance. In the generic body, we have explicit rules that essentially assume the worst (in the cases of type extensions and access-to-subprogram types), and we have run-time checks (in the case of access-to-object types). See 3.9.1, 3.10.2, and 4.6.
- 11.t
- We considered run-time checks for access-to-subprogram types as well. However, this would present difficulties for implementations that share generic bodies.
- 11.u
- The rules requiring “reasonable” values for static expressions are ignored when the expected type for the expression is a descendant of a generic formal type other than a generic formal derived type, and do not apply in an instance.
- 11.v
- The rule forbidding two explicit homographs in the same declarative region does not apply in an instance of a generic unit, except that it *does* apply in the declaration of a record extension that appears in the visible part of an instance.
- 11.w
- Some rules do not apply at all in an instance, not even in the visible part:

- `Body_stubs` are not normally allowed to be multiply nested, but they can be in instances. 11.x

Each rule that is an exception is marked with “generic contract issue;” look that up in the index to find them all. 11.y

Ramification: The Legality Rules are the ones labeled Legality Rules. We are talking about all Legality Rules in the entire language here. Note that, with some exceptions, the legality of a generic unit is checked even if there are no instantiations of the generic unit. 11.z

Ramification: *{AI05-0299-1}* The Legality Rules are described here, and the overloading rules were described earlier in this subclause. Presumably, every Static Semantic Item is sucked in by one of those. Thus, we have covered all the compile-time rules of the language. There is no need to say anything special about the Post-Compilation Rules or the Dynamic Semantic Items. 11.aa/3

Discussion: Here is an example illustrating how this rule is checked: “In the declaration of a record extension, if the parent type is nonlimited, then each of the components of the `record_extension_part` shall be nonlimited.” 11.bb

```
generic
  type Parent is tagged private;
  type Comp is limited private;
package G1 is
  type Extension is new Parent with
    record
      C : Comp; -- Illegal!
    end record;
end G1; 11.cc
```

The parent type is nonlimited, and the component type is limited, which is illegal. It doesn't matter that one could imagine writing an instantiation with the actual for `Comp` being nonlimited — we never get to the instance, because the generic itself is illegal. 11.dd/1

On the other hand: 11.ee

```
generic
  type Parent is tagged limited private; -- Parent is limited.
  type Comp is limited private;
package G2 is
  type Extension is new Parent with
    record
      C : Comp; -- OK.
    end record;
end G2; 11.ff
```

```
type Limited_Tagged is tagged limited null record; 11.gg
type Non_Limited_Tagged is tagged null record;
```

```
type Limited_Untagged is limited null record; 11.hh
type Non_Limited_Untagged is null record;
```

```
package Good_1 is new G2(Parent => Limited_Tagged, 11.ii
  Comp => Limited_Untagged);
package Good_2 is new G2(Parent => Non_Limited_Tagged,
  Comp => Non_Limited_Untagged);
package Bad is new G2(Parent => Non_Limited_Tagged,
  Comp => Limited_Untagged); -- Illegal!
```

The first instantiation is legal, because in the instance the parent is limited, so the rule is not violated. Likewise, in the second instantiation, the rule is not violated in the instance. However, in the `Bad` instance, the parent type is nonlimited, and the component type is limited, so this instantiation is illegal. 11.jj

Static Semantics

A `generic_instantiation` declares an instance; it is equivalent to the instance declaration (a `package_`-`declaration` or `subprogram_declaration`) immediately followed by the instance body, both at the place of the instantiation. 12

Ramification: The declaration and the body of the instance are not “implicit” in the technical sense, even though you can't see them in the program text. Nor are declarations within an instance “implicit” (unless they are implicit by other rules). This is necessary because implicit declarations have special semantics that should not be attached to instances. For a generic subprogram, the profile of a `generic_instantiation` is that of the instance declaration, by the stated equivalence. 12.a

Ramification: The visible and private parts of a package instance are defined in 7.1, “Package Specifications and Declarations” and 12.7, “Formal Packages”. The visible and private parts of a subprogram instance are defined in 8.2, “Scope of Declarations”. 12.b

- 13 The instance is a copy of the text of the template. [Each use of a formal parameter becomes (in the copy) a use of the actual, as explained below.] An instance of a generic package is a package, that of a generic procedure is a procedure, and that of a generic function is a function.
- 13.a **Ramification:** An instance is a package or subprogram (because we say so), even though it contains a copy of the `generic_formal_part`, and therefore doesn't look like one. This is strange, but it's OK, since the syntax rules are overloading rules, and therefore do not apply in an instance.
- 13.b **Discussion:** We use a macro-expansion model, with some explicitly-stated exceptions (see below). The main exception is that the interpretation of each construct in a generic unit (especially including the denotation of each name) is determined when the declaration and body of the generic unit (as opposed to the instance) are compiled, and in each instance this interpretation is (a copy of) the template interpretation. In other words, if a construct is interpreted as a name denoting a declaration *D*, then in an instance, the copy of the construct will still be a name, and will still denote *D* (or a copy of *D*). From an implementation point of view, overload resolution is performed on the template, and not on each copy.
- 13.c We describe the substitution of generic actual parameters by saying (in most cases) that the copy of each generic formal parameter declares a view of the actual. Suppose a name in a generic unit denotes a `generic_formal_parameter_declaration`. The copy of that name in an instance will denote the copy of that `generic_formal_parameter_declaration` in the instance. Since the `generic_formal_parameter_declaration` in the instance declares a view of the actual, the name will denote a view of the actual.
- 13.d/2 {A195-00442-01} Other properties of the copy (for example, staticness, categories to which types belong) are recalculated for each instance; this is implied by the fact that it's a copy.
- 13.e/2 {A195-00317-01} Although the `generic_formal_part` is included in an instance, the declarations in the `generic_formal_part` are only visible outside the instance in the case of a generic formal package whose `formal_package_actual_part` includes one or more `<>` indicators — see 12.7.
- 14 The interpretation of each construct within a generic declaration or body is determined using the overloading rules when that generic declaration or body is compiled. In an instance, the interpretation of each (copied) construct is the same, except in the case of a name that denotes the `generic_declaration` or some declaration within the generic unit; the corresponding name in the instance then denotes the corresponding copy of the denoted declaration. The overloading rules do not apply in the instance.
- 14.a **Ramification:** See 8.6, “The Context of Overload Resolution” for definitions of “interpretation” and “overloading rule.”
- 14.b Even the `generic_formal_parameter_declarations` have corresponding declarations in the instance, which declare views of the actuals.
- 14.c Although the declarations in the instance are copies of those in the generic unit, they often have quite different properties, as explained below. For example a constant declaration in the generic unit might declare a nonstatic constant, whereas the copy of that declaration might declare a static constant. This can happen when the staticness depends on some generic formal.
- 14.d This rule is partly a ramification of the “current instance” rule in 8.6, “The Context of Overload Resolution”. Note that that rule doesn't cover the `generic_formal_part`.
- 14.e Although the overloading rules are not observed in the instance, they are, of course, observed in the `_instantiation` in order to determine the interpretation of the constituents of the `_instantiation`.
- 14.f Since children are considered to occur within their parent's declarative region, the above rule applies to a name that denotes a child of a generic unit, or a declaration inside such a child.
- 14.g Since the Syntax Rules are overloading rules, it is possible (legal) to violate them in an instance. For example, it is possible for an instance body to occur in a `package_specification`, even though the Syntax Rules forbid bodies in `package_specifications`.
- 15 In an instance, a `generic_formal_parameter_declaration` declares a view whose properties are identical to those of the actual, except as specified in 12.4, “Formal Objects” and 12.6, “Formal Subprograms”. Similarly, for a declaration within a `generic_formal_parameter_declaration`, the corresponding declaration in an instance declares a view whose properties are identical to the corresponding declaration within the declaration of the actual.
- 15.a **Ramification:** In an instance, there are no “properties” of types and subtypes that come from the formal. The primitive operations of the type come from the formal, but these are declarations in their own right, and are therefore handled separately.

Note that certain properties that come from the actuals are irrelevant in the instance. For example, if an actual type is of a class deeper in the derived-type hierarchy than the formal, it is impossible to call the additional operations of the deeper class in the instance, because any such call would have to be a copy of some corresponding call in the generic unit, which would have been illegal. However, it is sometimes possible to reach into the specification of the instance from outside, and notice such properties. For example, one could pass an object declared in the instance specification to one of the additional operations of the deeper type. 15.b

{AI95-00114-01} A formal_type_declaration can contain discriminant_specifications, a formal_subprogram_declaration can contain parameter_specifications, and a formal_package_declaration can contain many kinds of declarations. These are all inside the generic unit, and have corresponding declarations in the instance. 15.c/2

This rule implies, for example, that if a subtype in a generic unit is a subtype of a generic formal subtype, then the corresponding subtype in the instance is a subtype of the corresponding actual subtype. 15.d

For a generic_instantiation, if a generic actual is a static [(scalar or string)] subtype, then each use of the corresponding formal parameter within the specification of the instance is considered to be static. (See AI83-00409.) 15.e

Similarly, if a generic actual is a static expression and the corresponding formal parameter has a static [(scalar or string)] subtype, then each use of the formal parameter in the specification of the instance is considered to be static. (See AI83-00505.) 15.f

If a primitive subprogram of a type derived from a generic formal derived tagged type is not overriding (that is, it is a new subprogram), it is possible for the copy of that subprogram in an instance to override a subprogram inherited from the actual. For example: 15.g

```

type T1 is tagged record ... end record;
generic
  type Formal is new T1;
package G is
  type Derived_From_Formals is new Formal with record ... end record;
  procedure Foo(X : in Derived_From_Formals); -- Does not override anything.
end G;

```

```

type T2 is new T1 with record ... end record;
procedure Foo(X : in T2);

```

```

package Inst is new G(Formal => T2);

```

In the instance Inst, the declaration of Foo for Derived_From_Formals overrides the Foo inherited from T2. 15.i

Implementation Note: {8652/0009} {AI95-00137-01} For formal types, an implementation that shares the code among multiple instances of the same generic unit needs to beware that things like parameter passing mechanisms (by-copy vs. by-reference) and aspect_clauses are determined by the actual. 15.m/1

[Implicit declarations are also copied, and a name that denotes an implicit declaration in the generic denotes the corresponding copy in the instance. However, for a type declared within the visible part of the generic, a whole new set of primitive subprograms is implicitly declared for use outside the instance, and may differ from the copied set if the properties of the type in some way depend on the properties of some actual type specified in the instantiation. For example, if the type in the generic is derived from a formal private type, then in the instance the type will inherit subprograms from the corresponding actual type. 16

These new implicit declarations occur immediately after the type declaration in the instance, and override the copied ones. The copied ones can be called only from within the instance; the new ones can be called only from outside the instance, although for tagged types, the body of a new one can be executed by a call to an old one.] 17

Proof: This rule is stated officially in 8.3, “Visibility”. 17.a

Ramification: The new ones follow from the class(es) of the formal types. For example, for a type T derived from a generic formal private type, if the actual is Integer, then the copy of T in the instance has a "+" primitive operator, which can be called from outside the instance (assuming T is declared in the visible part of the instance). 17.b

AI83-00398. 17.c

{AI95-00442-01} Since an actual type is always in the category determined for the formal, the new subprograms hide all of the copied ones, except for a declaration of "/" that corresponds to an explicit declaration of "/=". Such "/" operators are special, because unlike other implicit declarations of primitive subprograms, they do not appear by virtue of the class, but because of an explicit declaration of "/=". If the declaration of "/" is implicit (and therefore overridden in the instance), then a corresponding implicitly declared "/" is also overridden. But if the declaration of "/" is 17.d/2

explicit (and therefore not overridden in the instance), then a corresponding implicitly declared "/" is not overridden either, even though it's implicit.

17.e Note that the copied ones can be called from inside the instance, even though they are hidden from all visibility, because the names are resolved in the generic unit — visibility is irrelevant for calls in the instance.

18 [In the visible part of an instance, an explicit declaration overrides an implicit declaration if they are homographs, as described in 8.3.] On the other hand, an explicit declaration in the private part of an instance overrides an implicit declaration in the instance, only if the corresponding explicit declaration in the generic overrides a corresponding implicit declaration in the generic. Corresponding rules apply to the other kinds of overriding described in 8.3.

18.a **Ramification:** For example:

```
18.b     type Ancestor is tagged null record;
18.c     generic
         type Formal is new Ancestor with private;
         package G is
           type T is new Formal with null record;
           procedure P(X : in T); -- (1)
         private
           procedure Q(X : in T); -- (2)
         end G;
18.d     type Actual is new Ancestor with null record;
         procedure P(X : in Actual);
         procedure Q(X : in Actual);
18.e     package Instance is new G(Actual => Actual);
```

18.f In the instance, the copy of P at (1) overrides Actual's P, whereas the copy of Q at (2) does not override anything; in implementation terms, it occupies a separate slot in the type descriptor.

18.g **Reason:** The reason for this rule is so a programmer writing an `_instantiation` need not look at the private part of the generic in order to determine which subprograms will be overridden.

Post-Compilation Rules

19 Recursive generic instantiation is not allowed in the following sense: if a given generic unit includes an instantiation of a second generic unit, then the instance generated by this instantiation shall not include an instance of the first generic unit [(whether this instance is generated directly, or indirectly by intermediate instantiations)].

19.a **Discussion:** Note that this rule is not a violation of the generic contract model, because it is not a Legality Rule. Some implementations may be able to check this rule at compile time, but that requires access to all the bodies, so we allow implementations to check the rule at link time.

Dynamic Semantics

20 For the elaboration of a `generic_instantiation`, each `generic_association` is first evaluated. If a default is used, an implicit `generic_association` is assumed for this rule. These evaluations are done in an arbitrary order, except that the evaluation for a default actual takes place after the evaluation for another actual if the default includes a name that denotes the other one. Finally, the instance declaration and body are elaborated.

20.a **Ramification:** Note that if the evaluation of a default depends on some side effect of some other evaluation, the order is still arbitrary.

21 For the evaluation of a `generic_association` the generic actual parameter is evaluated. Additional actions are performed in the case of a formal object of mode `in` (see 12.4).

21.a **To be honest:** Actually, the actual is evaluated only if evaluation is defined for that kind of construct — we don't actually “evaluate” `subtype_marks`.

NOTES

22 5 If a formal type is not tagged, then the type is treated as an untagged type within the generic body. Deriving from such a type in a generic body is permitted; the new type does not get a new tag value, even if the actual is tagged. Overriding operations for such a derived type cannot be dispatched to from outside the instance.

Ramification: If two overloaded subprograms declared in a generic package specification differ only by the (formal) type of their parameters and results, then there exist legal instantiations for which all calls of these subprograms from outside the instance are ambiguous. For example: 22.a

```

generic
  type A is (<>);
  type B is private;
package G is
  function Next(X : A) return A;
  function Next(X : B) return B;
end G;
package P is new G(A => Boolean, B => Boolean);
-- All calls of P.Next are ambiguous.

```

22.b
22.c

Ramification: The following example illustrates some of the subtleties of the substitution of formals and actuals: 22.d

```

generic
  type T1 is private;
  -- A predefined "=" operator is implicitly declared here:
  -- function "(Left, Right : T1) return Boolean;
  -- Call this "=",

```

22.e

```

package G is
  subtype S1 is T1; -- So we can get our hands on the type from
                    -- outside an instance.
  type T2 is new T1;
  -- An inherited "=" operator is implicitly declared here:
  -- function "(Left, Right : T2) return Boolean;
  -- Call this "=",

```

```

T1_Obj : T1 := ...;
Bool_1 : Boolean := T1_Obj = T1_Obj;

```

22.f

```

T2_Obj : T2 := ...;
Bool_2 : Boolean := T2_Obj = T2_Obj;

```

22.g

```

end G;
...
package P is
  type My_Int is new Integer;
  -- A predefined "=" operator is implicitly declared here:
  -- function "(Left, Right : My_Int) return Boolean;
  -- Call this "=",

```

22.h

```

function "="(X, Y : My_Int) return Boolean;
-- Call this "=",
-- "="3 is hidden from all visibility by "=",
-- Nonetheless, "="3 can "reemerge" in certain circumstances.
end P;
use P;
...
package I is new G(T1 => My_Int); -- "="3 is declared in I (see below).
use I;

```

```

Another_T1_Obj : S1 := 13; -- Can't denote T1, but S1 will do.
Bool_3 : Boolean := Another_T1_Obj = Another_T1_Obj;

```

22.i

```

Another_T2_Obj : T2 := 45;
Bool_4 : Boolean := Another_T2_Obj = Another_T2_Obj;

```

22.j

```

Double : T2 := T2_Obj + Another_T2_Obj;

```

22.k

In the instance I, there is a copy of "="₁ (call it "="_{1i}) and "="₂ (call it "="_{2i}). The "="_{1i} and "="_{2i} declare views of the predefined "=" of My_Int (that is, "="₃). In the initialization of Bool_1 and Bool_2 in the generic unit G, the names "=" denote "="₁ and "="₂, respectively. Therefore, the copies of these names in the instances denote "="_{1i} and "="_{2i}, respectively. Thus, the initialization of I.Bool_1 and I.Bool_2 call the predefined equality operator of My_Int; they will not call "="₄. 22.l

The declarations "="_{1i} and "="_{2i} are hidden from all visibility. This prevents them from being called from outside the instance. 22.m

The declaration of Bool_3 calls "="₄. 22.n

The instance I also contains implicit declarations of the primitive operators of T2, such as "=" (call it "="₅) and "+". These operations cannot be called from within the instance, but the declaration of Bool_4 calls "="₅. 22.o

Examples

23 *Examples of generic instantiations (see 12.1):*

```
24 procedure Swap is new Exchange(Elem => Integer);
procedure Swap is new Exchange(Character); -- Swap is overloaded
function Square is new Squaring(Integer); -- "*" of Integer used by default
function Square is new Squaring(Item => Matrix, "*" => Matrix_Product);
function Square is new Squaring(Matrix, Matrix_Product); -- same as previous
25 package Int_Vectors is new On_Vectors(Integer, Table, "+");
```

26 *Examples of uses of instantiated units:*

```
27 Swap(A, B);
A := Square(A);
28 T : Table(1 .. 5) := (10, 20, 30, 40, 50);
N : Integer := Int_Vectors.Sigma(T); -- 150 (see 12.2, "Generic Bodies" for the body of Sigma)
29 use Int_Vectors;
M : Integer := Sigma(T); -- 150
```

Inconsistencies With Ada 83

29.a In Ada 83, all explicit actuals are evaluated before all defaults, and the defaults are evaluated in the order of the formal declarations. This ordering requirement is relaxed in Ada 95.

Incompatibilities With Ada 83

29.b We have attempted to remove every violation of the contract model. Any remaining contract model violations should be considered bugs in the RM95. The unfortunate property of reverting to the predefined operators of the actual types is retained for upward compatibility. (Note that fixing this would require subtype conformance rules.) However, tagged types do not revert in this sense.

Extensions to Ada 83

29.c The syntax rule for `explicit_generic_actual_parameter` is modified to allow a `package_instance_name`.

Wording Changes from Ada 83

29.d The fact that named associations cannot be used for two formal subprograms with the same defining name is moved to AARM-only material, because it is a ramification of other rules, and because it is not of interest to the average user.

29.e/2 *{AI95-00114-01}* The rule that “An explicit `explicit_generic_actual_parameter` shall not be supplied more than once for a given generic formal parameter” seems to be missing from RM83, although it was clearly the intent.

29.f In the explanation that the instance is a copy of the template, we have left out RM83-12.3(5)’s “apart from the generic formal part”, because it seems that things in the formal part still need to exist in instances. This is particularly true for generic formal packages, where you’re sometimes allowed to reach in and denote the formals of the formal package from outside it. This simplifies the explanation of what each name in an instance denotes: there are just two cases: the declaration can be inside or outside (where inside needs to include the generic unit itself). Note that the RM83 approach of listing many cases (see RM83-12.5(5-14)) would have become even more unwieldy with the addition of generic formal packages, and the declarations that occur therein.

29.g We have corrected the definition of the elaboration of a `generic_instantiation` (RM83-12.3(17)); we don’t elaborate entities, and the instance is not “implicit.”

29.h In RM83, there is a rule saying the formal and actual shall match, and then there is much text defining what it means to match. Here, we simply state all the latter text as rules. For example, “A formal foo is matched by an actual greenish bar” becomes “For a formal foo, the actual shall be a greenish bar.” This is necessary to split the Name Resolution Rules from the Legality Rules. Besides, there’s really no need to define the concept of matching for generic parameters.

Extensions to Ada 95

29.i/2 *{AI95-00218-03}* An `overriding_indicator` (see 8.3.1) is allowed on a subprogram instantiation.

Extensions to Ada 2005

29.j/3 *{AI05-0183-1}* An optional `aspect_specification` can be used in a `generic_instantiation`. This is described in 13.1.1.

Wording Changes from Ada 2005

{AI05-0118-1} **Correction:** Added a definition for positional parameters, as this is missing from Ada 95 and Ada 2005. 29.k/3

12.4 Formal Objects

[A generic formal object can be used to pass a value or variable to a generic unit.] 1

Language Design Principles

A generic formal object of mode **in** is like a constant initialized to the value of the `explicit_generic_actual_parameter`. 1.a

A generic formal object of mode **in out** is like a renaming of the `explicit_generic_actual_parameter`. 1.b

Syntax

```
{AI95-00423-01} {AI05-0005-1} {AI05-0183-1} formal_object_declaration ::=
  defining_identifier_list : mode [null_exclusion] subtype_mark [:= default_expression]
  [aspect_specification];
| defining_identifier_list : mode access_definition [:= default_expression]
  [aspect_specification];
```

2/3

Name Resolution Rules

The expected type for the `default_expression`, if any, of a formal object is the type of the formal object. 3

For a generic formal object of mode **in**, the expected type for the actual is the type of the formal. 4

{AI95-00423-01} For a generic formal object of mode **in out**, the type of the actual shall resolve to the type determined by the `subtype_mark`, or for a `formal_object_declaration` with an `access_definition`, to a specific anonymous access type. If the anonymous access type is an access-to-object type, the type of the actual shall have the same designated type as that of the `access_definition`. If the anonymous access type is an access-to-subprogram type, the type of the actual shall have a designated profile which is type conformant with that of the `access_definition`. 5/2

Reason: See the corresponding rule for `object_renaming_declarations` for a discussion of the reason for this rule. 5.a

Legality Rules

If a generic formal object has a `default_expression`, then the mode shall be **in** [(either explicitly or by default)]; otherwise, its mode shall be either **in** or **in out**. 6

Ramification: Mode **out** is not allowed for generic formal objects. 6.a

For a generic formal object of mode **in**, the actual shall be an `expression`. For a generic formal object of mode **in out**, the actual shall be a `name` that denotes a variable for which renaming is allowed (see 8.5.1). 7

To be honest: The part of this that requires an `expression` or `name` is a Name Resolution Rule, but that's too pedantic to worry about. (The part about denoting a variable, and renaming being allowed, is most certainly *not* a Name Resolution Rule.) 7.a

{AI95-00287-01} {AI95-00423-01} In the case where the type of the formal is defined by an `access_definition`, the type of the actual and the type of the formal: 8/2

- {AI95-00423-01} shall both be access-to-object types with statically matching designated subtypes and with both or neither being access-to-constant types; or 8.1/2
- {AI95-00423-01} shall both be access-to-subprogram types with subtype conformant designated profiles. 8.2/2

{AI95-00423-01} For a `formal_object_declaration` with a `null_exclusion` or an `access_definition` that has a `null_exclusion`: 8.3/2

- 8.4/2 • if the actual matching the `formal_object_declaration` denotes the generic formal object of another generic unit G , and the instantiation containing the actual occurs within the body of G or within the body of a generic unit declared within the declarative region of G , then the declaration of the formal object of G shall have a `null_exclusion`;
 - 8.5/2 • otherwise, the subtype of the actual matching the `formal_object_declaration` shall exclude null. In addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit.
- 8.a/2 **Reason:** {AI95-00287-01} {AI95-00423-01} This rule prevents “lying”. **Null** must never be the value of an object with an explicit `null_exclusion`. The first bullet is an assume-the-worst rule which prevents trouble in generic bodies (including bodies of child units) when the subtype of the formal object excludes null implicitly.

Static Semantics

- 9/2 {AI95-00255-01} {AI95-00423-01} A `formal_object_declaration` declares a generic formal object. The default mode is **in**. For a formal object of mode **in**, the nominal subtype is the one denoted by the `subtype_mark` or `access_definition` in the declaration of the formal. For a formal object of mode **in out**, its type is determined by the `subtype_mark` or `access_definition` in the declaration; its nominal subtype is nonstatic, even if the `subtype_mark` denotes a static subtype; for a composite type, its nominal subtype is unconstrained if the first subtype of the type is unconstrained[, even if the `subtype_mark` denotes a constrained subtype].
- 9.a/2 **Reason:** {AI95-00255-01} We require that the subtype is unconstrained because a formal **in out** acts like a renaming, and thus the given subtype is ignored for purposes of matching; any value of the type can be passed. Thus we can assume only that the object is constrained if the first subtype is constrained (and thus there can be no unconstrained subtypes for the type). If we didn't do this, it would be possible to rename or take 'Access of components that could disappear due to an assignment to the whole object.
- 9.b/2 **Discussion:** {AI95-00423-01} The two “even if” clauses are OK even though they don't mention `access_definitions`; an access subtype can neither be a static subtype nor be a composite type.
- 10/2 {AI95-00269-01} In an instance, a `formal_object_declaration` of mode **in** is a *full constant declaration* and declares a new stand-alone constant object whose initialization expression is the actual, whereas a `formal_object_declaration` of mode **in out** declares a view whose properties are identical to those of the actual.
- 10.a/2 **Ramification:** {AI95-00287-01} These rules imply that generic formal objects of mode **in** are passed by copy (or are built-in-place for a limited type), whereas generic formal objects of mode **in out** are passed by reference.
- 10.b Initialization and finalization happen for the constant declared by a `formal_object_declaration` of mode **in** as for any constant; see 3.3.1, “Object Declarations” and 7.6, “Assignment and Finalization”.
- 10.c In an instance, the subtype of a generic formal object of mode **in** is as for the equivalent constant. In an instance, the subtype of a generic formal object of mode **in out** is the subtype of the corresponding generic actual.

Dynamic Semantics

- 11 For the evaluation of a `generic_association` for a formal object of mode **in**, a constant object is created, the value of the actual parameter is converted to the nominal subtype of the formal object, and assigned to the object[, including any value adjustment — see 7.6].
- 11.a **Ramification:** This includes evaluating the actual and doing a subtype conversion, which might raise an exception.
- 11.b **Discussion:** The rule for evaluating a `generic_association` for a formal object of mode **in out** is covered by the general Dynamic Semantics rule in 12.3.

NOTES

- 12 6 The constraints that apply to a generic formal object of mode **in out** are those of the corresponding generic actual parameter (not those implied by the `subtype_mark` that appears in the `formal_object_declaration`). Therefore, to avoid confusion, it is recommended that the name of a first subtype be used for the declaration of such a formal object.
- 12.a **Ramification:** Constraint checks are done at instantiation time for formal objects of mode **in**, but not for formal objects of mode **in out**.

Extensions to Ada 83

In Ada 83, it is forbidden to pass a (nongeneric) formal parameter of mode **out**, or a subcomponent thereof, to a generic formal object of mode **in out**. This restriction is removed in Ada 95. 12.b

Wording Changes from Ada 83

We make “mode” explicit in the syntax. RM83 refers to the mode without saying what it is. This is also more uniform with the way (nongeneric) formal parameters are defined. 12.c

We considered allowing mode **out** in Ada 95, for uniformity with (nongeneric) formal parameters. The semantics would be identical for modes **in out** and **out**. (Note that generic formal objects of mode **in out** are passed by reference. Note that for (nongeneric) formal parameters that are allowed to be passed by reference, the semantics of **in out** and **out** is the same. The difference might serve as documentation. The same would be true for generic formal objects, if **out** were allowed, so it would be consistent.) We decided not to make this change, because it does not produce any important benefit, and any change has some cost. 12.d

Extensions to Ada 95

{AI95-00287-01} A generic formal **in** object can have a limited type. The actual for such an object must be built-in-place via a `function_call` or `aggregate`, see 7.5. 12.e/2

{AI95-00423-01} A generic formal object can have a `null_exclusion` or an anonymous access type. 12.f/2

Wording Changes from Ada 95

{AI95-00255-01} Clarified that the nominal subtype of a composite formal **in out** object is unconstrained if the first subtype of the type is unconstrained. 12.g/2

{AI95-00269-01} Clarified that a formal **in** object can be static when referenced from outside of the instance (by declaring such an object to be a full constant declaration). 12.h/2

Extensions to Ada 2005

{AI05-0183-1} An optional `aspect_specification` can be used in a `formal_object_declaration`. This is described in 13.1.1. 12.i/3

12.5 Formal Types

{AI95-00442-01} [A generic formal subtype can be used to pass to a generic unit a subtype whose type is in a certain category of types.] 1/2

Reason: We considered having intermediate syntactic categories `formal_integer_type_definition`, `formal_real_type_definition`, and `formal_fixed_point_definition`, to be more uniform with the syntax rules for non-generic-formal types. However, that would make the rules for formal types slightly more complicated, and it would cause confusion, since `formal_discrete_type_definition` would not fit into the scheme very well. 1.a

Syntax

```
{AI05-0213-1} formal_type_declaration ::=
    formal_complete_type_declaration
  | formal_incomplete_type_declaration 2/3
```

```
{AI05-0183-1} {AI05-0213-1} formal_complete_type_declaration ::=
    type_defining_identifier[discriminant_part] is formal_type_definition
    [aspect_specification]; 2.1/3
```

```
{AI05-0213-1} formal_incomplete_type_declaration ::=
    type_defining_identifier[discriminant_part] [is tagged]; 2.2/3
```

3/2 `{AI95-00251-01}` `formal_type_definition ::=`
`formal_private_type_definition`
`| formal_derived_type_definition`
`| formal_discrete_type_definition`
`| formal_signed_integer_type_definition`
`| formal_modular_type_definition`
`| formal_floating_point_definition`
`| formal_ordinary_fixed_point_definition`
`| formal_decimal_fixed_point_definition`
`| formal_array_type_definition`
`| formal_access_type_definition`
`| formal_interface_type_definition`

Legality Rules

- 4 For a generic formal subtype, the actual shall be a `subtype_mark`; it denotes the (*generic*) *actual subtype*.
- 4.a **Ramification:** When we say simply “formal” or “actual” (for a generic formal that denotes a subtype) we’re talking about the subtype, not the type, since a name that denotes a `formal_type_declaration` denotes a subtype, and the corresponding actual also denotes a subtype.

Static Semantics

- 5 A `formal_type_declaration` declares a (*generic*) *formal type*, and its first subtype, the (*generic*) *formal subtype*.
- 5.a **Ramification:** A subtype (other than the first subtype) of a generic formal type is not a generic formal subtype.
- 6/3 `{AI95-00442-01}` `{AI05-0213-1}` The form of a `formal_type_definition` *determines a category (of types)* to which the formal type belongs. For a `formal_private_type_definition` the reserved words **tagged** and **limited** indicate the category of types (see 12.5.1). The reserved word **tagged** also plays this role in the case of a `formal_incomplete_type_declaration`. For a `formal_derived_type_definition` the category of types is the derivation class rooted at the ancestor type. For other formal types, the name of the syntactic category indicates the category of types; a `formal_discrete_type_definition` defines a discrete type, and so on.
- 6.a **Reason:** This rule is clearer with the flat syntax rule for `formal_type_definition` given above. Adding `formal_integer_type_definition` and others would make this rule harder to state clearly.
- 6.b/2 `{AI95-00442-01}` We use “category” rather than “class” above, because the requirement that classes are closed under derivation is not important here. Moreover, there are interesting categories that are not closed under derivation. For instance, limited and interface are categories that do not form classes.

Legality Rules

- 7/2 `{AI95-00442-01}` The actual type shall be in the category determined for the formal.
- 7.a/2 **Ramification:** `{AI95-00442-01}` For example, if the category determined for the formal is the category of all discrete types, then the actual has to be discrete.
- 7.b/2 `{AI95-00442-01}` Note that this rule does not require the actual to belong to every category to which the formal belongs. For example, formal private types are in the category of composite types, but the actual need not be composite. Furthermore, one can imagine an infinite number of categories that are just arbitrary sets of types (even though we don’t give them names, since they are uninteresting). We don’t want this rule to apply to *those* categories.
- 7.c/2 `{AI95-00114-01}` `{AI95-00442-01}` “Limited” is not an “interesting” category, but “nonlimited” is; it is legal to pass a nonlimited type to a limited formal type, but not the other way around. The reserved word **limited** really represents a category containing both limited and nonlimited types. “Private” is not a category for this purpose; a generic formal private type accepts both private and nonprivate actual types.
- 7.d/2 `{AI95-00442-01}` It is legal to pass a class-wide subtype as the actual if it is in the right category, so long as the formal has unknown discriminants.

Static Semantics

{8652/0037} {AI95-00043-01} {AI95-00233-01} {AI95-00442-01} {AI05-0029-1} [The formal type also belongs to each category that contains the determined category.] The primitive subprograms of the type are as for any type in the determined category. For a formal type other than a formal derived type, these are the predefined operators of the type. For an elementary formal type, the predefined operators are implicitly declared immediately after the declaration of the formal type. For a composite formal type, the predefined operators are implicitly declared either immediately after the declaration of the formal type, or later immediately within the declarative region in which the type is declared according to the rules of 7.3.1. In an instance, the copy of such an implicit declaration declares a view of the predefined operator of the actual type, even if this operator has been overridden for the actual type and even if it is never declared for the actual type. [The rules specific to formal derived types are given in 12.5.1.] 8/3

Ramification: {AI95-00442-01} All properties of the type are as for any type in the category. Some examples: The primitive operations available are as defined by the language for each category. The form of constraint applicable to a formal type in a `subtype_indication` depends on the category of the type as for a nonformal type. The formal type is tagged if and only if it is declared as a tagged private type, or as a type derived from a (visibly) tagged type. (Note that the actual type might be tagged even if the formal type is not.) 8.a/2

Reason: {AI05-0029-1} The somewhat cryptic phrase “even if it is never declared” is intended to deal with the following oddity: 8.b/3

```
package Q is
  type T is limited private;
private
  type T is range 1 .. 10;
end Q; 8.c/3
```

```
generic
  type A is array (Positive range <>) of T; 8.d/3
```

```
package Q.G is
  A1, A2 : A (1 .. 1);
private
  B : Boolean := A1 = A2;
end Q.G; 8.e/3
```

```
with Q.G; 8.e/3
```

```
package R is
  type C is array (Positive range <>) of Q.T;
  package I is new Q.G (C); -- Where is the predefined "=" for C?
end R; 8.f/3
```

An “=” is available for the formal type A in the private part of Q.G. However, no “=” operator is ever declared for type C, because its component type Q.T is limited. Still, in the instance I the name “=” declares a view of the “=” for C which exists-but-is-never-declared. 8.g/3

NOTES

7 Generic formal types, like all types, are not named. Instead, a name can denote a generic formal subtype. Within a generic unit, a generic formal type is considered as being distinct from all other (formal or nonformal) types. 9

Proof: This follows from the fact that each `formal_type_declaration` declares a type. 9.a

8 A `discriminant_part` is allowed only for certain kinds of types, and therefore only for certain kinds of generic formal types. See 3.7. 10

Ramification: The term “formal floating point type” refers to a type defined by a `formal_floating_point_definition`. It does not include a formal derived type whose ancestor is floating point. Similar terminology applies to the other kinds of `formal_type_definition`. 10.a

Examples

Examples of generic formal types: 11

```
type Item is private;
type Buffer (Length : Natural) is limited private; 12
```

```
type Enum is (<>);
type Int is range <>;
type Angle is delta <>;
type Mass is digits <>; 13
```

14 **type** Table **is array** (Enum) **of** Item;

15 *Example of a generic formal part declaring a formal integer type:*

```
16        generic
          type Rank is range <>;
          First  : Rank := Rank'First;
          Second : Rank := First + 1;  -- the operator "+" of the type Rank
```

Wording Changes from Ada 83

16.a RM83 has separate sections “Generic Formal Xs” and “Matching Rules for Formal Xs” (for various X's) with most of the text redundant between the two. We have combined the two in order to reduce the redundancy. In RM83, there is no “Matching Rules for Formal Types” section; nor is there a “Generic Formal Y Types” section (for Y = Private, Scalar, Array, and Access). This causes, for example, the duplication across all the “Matching Rules for Y Types” sections of the rule that the actual passed to a formal type shall be a subtype; the new organization avoids that problem.

16.b The matching rules are stated more concisely.

16.c We no longer consider the multiplying operators that deliver a result of type *universal_fixed* to be predefined for the various types; there is only one of each in package Standard. Therefore, we need not mention them here as RM83 had to.

Wording Changes from Ada 95

16.d/2 {8652/0037} {AI95-00043-01} {AI95-00233-01} Corrigendum 1 corrected the wording to properly define the location where operators are defined for formal array types. The wording here was inconsistent with that in 7.3.1, “Private Operations”. For the Amendment, this wording was corrected again, because it didn't reflect the Corrigendum 1 revisions in 7.3.1.

16.e/2 {AI95-00251-01} Formal interface types are defined; see 12.5.5, “Formal Interface Types”.

16.f/2 {AI95-00442-01} We use “determines a category” rather than class, since not all interesting properties form a class.

Extensions to Ada 2005

16.g/3 {AI05-0183-1} An optional `aspect_specification` can be used in a `formal_type_declaration`. This is described in 13.1.1.

Wording Changes from Ada 2005

16.h/3 {AI05-0029-1} **Correction:** Updated the wording to acknowledge the possibility of operations that are never declared for an actual type but still can be used inside of a generic unit.

16.i/3 {AI05-0213-1} {AI05-0299-1} Formal incomplete types are added; these are documented as an extension in the next subclause.

12.5.1 Formal Private and Derived Types

1/3 {AI95-00442-01} {AI05-0213-1} [In its most general form, the category determined for a formal private type is all types, but the category can be restricted to only nonlimited types or to only tagged types. Similarly, the category for a formal incomplete type is all types but the category can be restricted to only tagged types; unlike other formal types, the actual type does not need to be able to be frozen (see 13.14). The category determined for a formal derived type is the derivation class rooted at the ancestor type.]

1.a/3 **Proof:** {AI95-00442-01} {AI05-0213-1} The first two rules are given normatively below, and the third rule is given normatively in 12.5; they are repeated here to give a capsule summary of what this subclause is about.

1.b/3 **Ramification:** {AI05-0213-1} Since the actual of a formal incomplete type does not need to be able to be frozen, the actual can be an incomplete type or a partial view before its completion.

Syntax

2 `formal_private_type_definition ::= [[abstract] tagged] [limited] private`

3/2 {AI95-00251-01} {AI95-00419-01} {AI95-00443-01} `formal_derived_type_definition ::=`
 `[abstract] [limited | synchronized] new subtype_mark [[and interface_list]with private]`

Legality Rules

- If a generic formal type declaration has a `known_discriminant_part`, then it shall not include a `default_expression` for a discriminant. 4
- Ramification:** Consequently, a generic formal subtype with a `known_discriminant_part` is an indefinite subtype, so the declaration of a stand-alone variable has to provide a constraint on such a subtype, either explicitly, or by its initial value. 4.a
- {AI95-00401-01} {AI95-00419-01} {AI95-00443-01} {AI05-0237-1} The *ancestor subtype* of a formal derived type is the subtype denoted by the `subtype_mark` of the `formal_derived_type_definition`. For a formal derived type declaration, the reserved words **with private** shall appear if and only if the ancestor type is a tagged type; in this case the formal derived type is a private extension of the ancestor type and the ancestor shall not be a class-wide type. [Similarly, an `interface_list` or the optional reserved words **abstract** or **synchronized** shall appear only if the ancestor type is a tagged type]. The reserved word **limited** or **synchronized** shall appear only if the ancestor type [and any progenitor types] are limited types. The reserved word **synchronized** shall appear (rather than **limited**) if the ancestor type or any of the progenitor types are synchronized interfaces. The ancestor type shall be a limited interface if the reserved word **synchronized** appears. 5/3
- Reason:** We use the term “ancestor” here instead of “parent” because the actual can be any descendant of the ancestor, not necessarily a direct descendant. 5.a
- {AI95-00419-01} {AI05-0005-1} We require the ancestor type to be limited when **limited** appears so that we avoid oddities like limited integer types. Normally, **limited** means “match anything” for a generic formal, but it was felt that allowing limited elementary types to be declared was just too weird. Integer still matches a formal limited private type; it is only a problem when the type is known to be elementary. Note that the progenitors are required to be limited by rules in 3.9.4, thus that part of the rule is redundant. 5.b/3
- {AI95-00443-01} We require that **synchronized** appear if the ancestor or any of the progenitors are synchronized, so that property is explicitly given in the program text – it is not automatically inherited from the ancestors. However, it can be given even if neither the ancestor nor the progenitors are synchronized. 5.c/2
- {AI95-00251-01} {AI95-00401-01} {AI95-00443-01} {AI05-0087-1} The actual type for a formal derived type shall be a descendant of [the ancestor type and] every progenitor of the formal type. If the formal type is nonlimited, the actual type shall be nonlimited. If the reserved word **synchronized** appears in the declaration of the formal derived type, the actual type shall be a synchronized tagged type. 5.1/3
- Proof:** The actual type has to be a descendant of the ancestor type, in order that it be in the correct class. Thus, that part of the rule is redundant. 5.d/2
- Discussion:** {AI05-0005-1} For a nonformal private extension, we require the partial view to be synchronized if the full view is synchronized tagged. This does not apply to a formal private extension — it is OK if the formal is not synchronized. Any attempt to extend the formal type will be rechecked in the instance, where the rule disallowing extending a synchronized noninterface type will be enforced. This is consistent with the “no hidden interfaces” rule also applying only to nonformal private extensions, as well as the rule that a limited nonformal private extension implies a limited full type. Formal private extensions are exempted from all these rules to enable the construction of generics that can be used with the widest possible range of types. In particular, an indefinite tagged limited formal private type can match any “concrete” actual tagged type. 5.e/3
- {AI05-0087-1} A type (including formal types) derived from a limited interface could be nonlimited; we do not want a limited type derived from such an interface to match a nonlimited formal derived type. Otherwise, we could assign limited objects. Thus, we have to explicitly ban this case. 5.f/3
- {AI05-0213-1} If a formal private or derived subtype is definite, then the actual subtype shall also be definite. 6/3
- Ramification:** On the other hand, for an indefinite formal subtype, the actual can be either definite or indefinite. 6.a
- {AI05-0213-1} A `formal_incomplete_type_declaration` declares a formal incomplete type. The only view of a formal incomplete type is an incomplete view. [Thus, a formal incomplete type is subject to the same usage restrictions as any other incomplete type — see 3.10.1.] 6.1/3
- For a generic formal derived type with no `discriminant_part`: 7

- 8 • If the ancestor subtype is constrained, the actual subtype shall be constrained, and shall be statically compatible with the ancestor;
- 8.a **Ramification:** In other words, any constraint on the ancestor subtype is considered part of the “contract.”
- 9 • If the ancestor subtype is an unconstrained access or composite subtype, the actual subtype shall be unconstrained.
- 9.a **Reason:** This rule ensures that if a composite constraint is allowed on the formal, one is also allowed on the actual. If the ancestor subtype is an unconstrained scalar subtype, the actual is allowed to be constrained, since a scalar constraint does not cause further constraints to be illegal.
- 10 • If the ancestor subtype is an unconstrained discriminated subtype, then the actual shall have the same number of discriminants, and each discriminant of the actual shall correspond to a discriminant of the ancestor, in the sense of 3.7.
- 10.a **Reason:** This ensures that if a discriminant constraint is given on the formal subtype, the corresponding constraint in the instance will make sense, without additional run-time checks. This is not necessary for arrays, since the bounds cannot be overridden in a type extension. An `unknown_discriminant_part` may be used to relax these matching requirements.
- 10.1/2 • *{AI95-00231-01}* If the ancestor subtype is an access subtype, the actual subtype shall exclude null if and only if the ancestor subtype excludes null.
- 10.b/2 **Reason:** We require that the “excludes null” property match, because it would be difficult to write a correct generic for a formal access type without knowing this property. Many typical algorithms and techniques will not work for a subtype that excludes null (setting an unused component to `null`, default-initialized objects, and so on). We want this sort of requirement to be reflected in the contract of the generic.
- 11/3 *{AI05-0213-1}* The declaration of a formal derived type shall not have a `known_discriminant_part`. For a generic formal private or incomplete type with a `known_discriminant_part`:
 - 12 • The actual type shall be a type with the same number of discriminants.
 - 13 • The actual subtype shall be unconstrained.
 - 14 • The subtype of each discriminant of the actual type shall statically match the subtype of the corresponding discriminant of the formal type.
- 14.a **Reason:** We considered defining the first and third rule to be called “subtype conformance” for `discriminant_parts`. We rejected that idea, because it would require implicit (inherited) `discriminant_parts`, which seemed like too much mechanism.
- 15 [For a generic formal type with an `unknown_discriminant_part`, the actual may, but need not, have discriminants, and may be definite or indefinite.]

Static Semantics

16/2 *{AI95-00442-01}* The category determined for a formal private type is as follows:

<i>Type Definition</i>	<i>Determined Category</i>
limited private	the category of all types
private	the category of all nonlimited types
tagged limited private	the category of all tagged types
tagged private	the category of all nonlimited tagged types

18 [The presence of the reserved word **abstract** determines whether the actual type may be abstract.]

18.1/3 *{AI05-0213-1}* The category determined for a formal incomplete type is the category of all types, unless the `formal_type_declaration` includes the reserved word **tagged**; in this case, it is the category of all tagged types.

A formal private or derived type is a private or derived type, respectively. A formal derived tagged type is a private extension. [A formal private or derived type is abstract if the reserved word **abstract** appears in its declaration.] 19

{AI95-00233-01} {AI05-0110-1} For a formal derived type, the characteristics (including components, but excluding discriminants if there is a new `discriminant_part`), predefined operators, and inherited user-defined primitive subprograms are determined by its ancestor type and its progenitor types (if any), in the same way that those of a derived type are determined by those of its parent type and its progenitor types (see 3.4 and 7.3.1). 20/3

{8652/0038} {AI95-00202} {AI95-00233-01} {AI95-00401-01} {AI05-0029-1} {AI05-0110-1} In an instance, the copy of an implicit declaration of a primitive subprogram of a formal derived type declares a view of the corresponding primitive subprogram of the ancestor or progenitor of the formal derived type, even if this primitive has been overridden for the actual type and even if it is never declared for the actual type. When the ancestor or progenitor of the formal derived type is itself a formal type, the copy of the implicit declaration declares a view of the corresponding copied operation of the ancestor or progenitor. [In the case of a formal private extension, however, the tag of the formal type is that of the actual type, so if the tag in a call is statically determined to be that of the formal type, the body executed will be that corresponding to the actual type.] 21/3

Ramification: {AI95-00401-01} {AI05-0239-1} The above rule defining the properties of primitive subprograms in an instance applies even if the subprogram has been overridden or hidden for the actual type. This rule is necessary for untagged types, because their primitive subprograms might have been overridden by operations that are not subtype conformant with the operations defined for the class. For tagged types, the rule still applies, but the primitive subprograms will dispatch to the appropriate implementation based on the type and tag of the operands. Even for tagged types, the formal parameter names and `default_expressions` are determined by those of the primitive subprograms of the specified ancestor type (or progenitor type, for subprograms inherited from an interface type). 21.a/3

For a prefix `S` that denotes a formal indefinite subtype, the following attribute is defined: 22/1

`S'Definite` {AI05-0264-1} `S'Definite` yields `True` if the actual subtype corresponding to `S` is definite; otherwise, it yields `False`. The value of this attribute is of the predefined type `Boolean`. 23/3

Discussion: {AI95-00114-01} Whether an actual subtype is definite or indefinite may have a major effect on the algorithm used in a generic. For example, in a generic I/O package, whether to use fixed-length or variable-length records could depend on whether the actual is definite or indefinite. This attribute is essentially a replacement for the `Constrained` attribute, which is now considered obsolete. 23.a/2

Dynamic Semantics

{AI95-00158-01} {AI05-0071-1} In the case where a formal type has unknown discriminants, and the actual type is a class-wide type `TClass`: 23.1/3

- {AI95-00158-01} For the purposes of defining the primitive operations of the formal type, each of the primitive operations of the actual type is considered to be a subprogram (with an intrinsic calling convention — see 6.3.1) whose body consists of a dispatching call upon the corresponding operation of `T`, with its formal parameters as the actual parameters. If it is a function, the result of the dispatching call is returned. 23.2/2
- {AI95-00158-01} If the corresponding operation of `T` has no controlling formal parameters, then the controlling tag value is determined by the context of the call, according to the rules for tag-indeterminate calls (see 3.9.2 and 5.2). In the case where the tag would be statically determined to be that of the formal type, the call raises `Program_Error`. If such a function is renamed, any call on the renaming raises `Program_Error`. 23.3/2

Discussion: As it states in 6.3.1, the convention of an inherited subprogram of a generic formal tagged type with unknown discriminants is intrinsic. 23.b/2

In the case of a corresponding primitive of `T` with no controlling formal parameters, the context of the call provides the controlling tag value for the dispatch. If no tag is provided by context, `Program_Error` is raised rather than resorting to a nondispatching call. For example: 23.c/2

```

23.d/2      generic
            type NT(<>) is new T with private;
            -- Assume T has operation "function Empty return T;"
            package G is
            procedure Test(X : in out NT);
            end G;

23.e/2      package body G is
            procedure Test(X : in out NT) is
            begin
            X := Empty; -- Dispatching based on X'Tag takes
            -- place if actual is class-wide.

            declare
            Y : NT := Empty;
            -- If actual is class-wide, this raises Program_Error
            -- as there is no tag provided by context.

            begin
            X := Y; -- We never get this far.
            end;
            end Test;
            end G;

23.f/2      type T1 is new T with null record;
            package I is new G(T1'Class);

```

NOTES

- 24/2 9 {AI95-00442-01} In accordance with the general rule that the actual type shall belong to the category determined for the formal (see 12.5, “Formal Types”):
- 25 • If the formal type is nonlimited, then so shall be the actual;
 - 26 • For a formal derived type, the actual shall be in the class rooted at the ancestor subtype.
- 27 10 The actual type can be abstract only if the formal type is abstract (see 3.9.3).
- 27.a **Reason:** This is necessary to avoid contract model problems, since one or more of its primitive subprograms are abstract; it is forbidden to create objects of the type, or to declare functions returning the type.
- 27.b **Ramification:** On the other hand, it is OK to pass a nonabstract actual to an abstract formal — **abstract** on the formal indicates that the actual might be abstract.
- 28 11 If the formal has a `discriminant_part`, the actual can be either definite or indefinite. Otherwise, the actual has to be definite.

Incompatibilities With Ada 83

- 28.a Ada 83 does not have `unknown_discriminant_parts`, so it allows indefinite subtypes to be passed to definite formals, and applies a legality rule to the instance body. This is a contract model violation. Ada 95 disallows such cases at the point of the instantiation. The workaround is to add (\diamond) as the `discriminant_part` of any formal subtype if it is intended to be used with indefinite actuals. If that's the intent, then there can't be anything in the generic body that would require a definite subtype.
- 28.b The check for discriminant subtype matching is changed from a run-time check to a compile-time check.

Extensions to Ada 95

- 28.c/2 {AI95-00251-01} {AI95-00401-01} {AI95-00419-01} {AI95-00443-01} A generic formal derived type can include progenitors (interfaces) as well as a primary ancestor. It also may include **limited** to indicate that it is a limited type, and **synchronized** to indicate that it is a synchronized type.

Wording Changes from Ada 95

- 28.d/2 {8652/0038} {AI95-00202-01} **Corrigendum:** Corrected wording to define the operations that are inherited when the ancestor of a formal type is itself a formal type to avoid anomalies.
- 28.e/2 {AI95-00158-01} Added a semantic description of the meaning of operations of an actual class-wide type, as such a type does not have primitive operations of its own.
- 28.f/2 {AI95-00231-01} Added a matching rule for access subtypes that exclude null.
- 28.g/2 {AI95-00233-01} The wording for the declaration of implicit operations is corrected to be consistent with 7.3.1 as modified by Corrigendum 1.
- 28.h/2 {AI95-00442-01} We change to “determines a category” as that is the new terminology (it avoids confusion, since not all interesting properties form a class).

Incompatibilities With Ada 2005

{AI05-0087-1} **Correction:** Added wording to prevent a limited type from being passed to a nonlimited formal derived type. While this was allowed, it would break the contract for the limited type, so hopefully no programs actually depend on that. 28.l/3

Extensions to Ada 2005

{AI05-0213-1} Formal incomplete types are a new kind of generic formal; these can be instantiated with incomplete types and unfrozen private types. 28.j/3

Wording Changes from Ada 2005

{AI05-0029-1} **Correction:** Updated the wording to acknowledge the possibility of operations that are never declared for an actual type but still can be used inside of a generic unit. 28.k/3

{AI05-0071-1} **Correction:** Fixed hole that failed to define what happened for "=" for an untagged private type whose actual is class-wide. 28.l/3

{AI05-0110-1} **Correction:** Revised the wording for inheritance of characteristics and operations of formal derived types to be reuse the rules as defined for derived types; this should eliminate holes in the wording which have plagued us since Ada 95 was defined (it has been "corrected" four previous times). 28.m/3

{AI05-0237-1} **Correction:** Added missing rule for the ancestors of formal derived types. The added rule would formally be incompatible, but since it would be impossible to instantiate any such generic, this cannot happen outside of test suites and thus is not documented as an incompatibility. 28.n/3

12.5.2 Formal Scalar Types

{AI95-00442-01} A *formal scalar type* is one defined by any of the `formal_type_definitions` in this subclause. [The category determined for a formal scalar type is the category of all discrete, signed integer, modular, floating point, ordinary fixed point, or decimal types.] 1/2

Proof: {AI95-00442-01} The second rule follows from the rule in 12.5 that says that the category is determined by the one given in the name of the syntax production. The effect of the rule is repeated here to give a capsule summary of what this subclause is about. 1.a/2

Ramification: {AI95-00442-01} The “category of a type” includes any classes that the type belongs to. 1.b/2

Syntax

`formal_discrete_type_definition ::= (<>)` 2

`formal_signed_integer_type_definition ::= range <>` 3

`formal_modular_type_definition ::= mod <>` 4

`formal_floating_point_definition ::= digits <>` 5

`formal_ordinary_fixed_point_definition ::= delta <>` 6

`formal_decimal_fixed_point_definition ::= delta <> digits <>` 7

Legality Rules

The actual type for a formal scalar type shall not be a nonstandard numeric type. 8

Reason: This restriction is necessary because nonstandard numeric types have some number of restrictions on their use, which could cause contract model problems in a generic body. Note that nonstandard numeric types can be passed to formal derived and formal private subtypes, assuming they obey all the other rules, and assuming the implementation allows it (being nonstandard means the implementation might disallow anything). 8.a

NOTES

12 The actual type shall be in the class of types implied by the syntactic category of the formal type definition (see 12.5, “Formal Types”). For example, the actual for a `formal_modular_type_definition` shall be a modular type. 9

Wording Changes from Ada 95

{AI95-00442-01} We change to “determines a category” as that is the new terminology (it avoids confusion, since not all interesting properties form a class). 9.a/2

12.5.3 Formal Array Types

1/2 {AI95-00442-01} [The category determined for a formal array type is the category of all array types.]

1.a/2 **Proof:** {AI95-00442-01} This rule follows from the rule in 12.5 that says that the category is determined by the one given in the name of the syntax production. The effect of the rule is repeated here to give a capsule summary of what this subclause is about.

Syntax

2 formal_array_type_definition ::= array_type_definition

Legality Rules

3 The only form of discrete_subtype_definition that is allowed within the declaration of a generic formal (constrained) array subtype is a subtype_mark.

3.a **Reason:** The reason is the same as for forbidding constraints in subtype_indications (see 12.1).

4 For a formal array subtype, the actual subtype shall satisfy the following conditions:

- 5 • The formal array type and the actual array type shall have the same dimensionality; the formal subtype and the actual subtype shall be either both constrained or both unconstrained.
- 6 • For each index position, the index types shall be the same, and the index subtypes (if unconstrained), or the index ranges (if constrained), shall statically match (see 4.9.1).
- 7 • The component subtypes of the formal and actual array types shall statically match.
- 8 • If the formal type has aliased components, then so shall the actual.

8.a **Ramification:** On the other hand, if the formal's components are not aliased, then the actual's components can be either aliased or not.

Examples

9 *Example of formal array types:*

```
10 -- given the generic package
11 generic
   type Item is private;
   type Index is (<>);
   type Vector is array (Index range <>) of Item;
   type Table is array (Index) of Item;
package P is
   ...
end P;
12 -- and the types
13 type Mix is array (Color range <>) of Boolean;
   type Option is array (Color) of Boolean;
14 -- then Mix can match Vector and Option can match Table
15 package R is new P(Item => Boolean, Index => Color,
   Vector => Mix, Table => Option);
16 -- Note that Mix cannot match Table and Option cannot match Vector
```

Incompatibilities With Ada 83

16.a The check for matching of component subtypes and index subtypes or index ranges is changed from a run-time check to a compile-time check. The Ada 83 rule that “If the component type is not a scalar type, then the component subtypes shall be either both constrained or both unconstrained” is removed, since it is subsumed by static matching. Likewise, the rules requiring that component types be the same is subsumed.

Wording Changes from Ada 95

{AI95-00442-01} We change to “determines a category” as that is the new terminology (it avoids confusion, since not all interesting properties form a class). 16.b/2

12.5.4 Formal Access Types

{AI95-00442-01} [The category determined for a formal access type is the category of all access types.] 1/2

Proof: {AI95-00442-01} This rule follows from the rule in 12.5 that says that the category is determined by the one given in the name of the syntax production. The effect of the rule is repeated here to give a capsule summary of what this subclause is about. 1.a/2

Syntax

formal_access_type_definition ::= access_type_definition 2

Legality Rules

For a formal access-to-object type, the designated subtypes of the formal and actual types shall statically match. 3

{AI95-00231-01} If and only if the **general_access_modifier constant** applies to the formal, the actual shall be an access-to-constant type. If the **general_access_modifier all** applies to the formal, then the actual shall be a general access-to-variable type (see 3.10). If and only if the formal subtype excludes null, the actual subtype shall exclude null. 4/2

Ramification: If no **_modifier** applies to the formal, then the actual type may be either a pool-specific or a general access-to-variable type. 4.a

Reason: {8652/0109} {AI95-00025-01} Matching an access-to-variable to a formal access-to-constant type cannot be allowed. If it were allowed, it would be possible to create an access-to-variable value designating a constant. 4.a.1/1

{AI95-00231-01} We require that the “excludes null” property match, because it would be difficult to write a correct generic for a formal access type without knowing this property. Many typical algorithms and techniques will not work for a subtype that excludes null (setting an unused component to **null**, default-initialized objects, and so on). Even `Ada.Unchecked_Deallocation` would fail for a subtype that excludes null. Most generics would end up with comments saying that they are not intended to work for subtypes that exclude null. We would rather that this sort of requirement be reflected in the contract of the generic. 4.b/2

{AI05-0239-1} {AI05-0288-1} For a formal access-to-subprogram subtype, the designated profiles of the formal and the actual shall be subtype conformant. 5/3

Examples

Example of formal access types: 6

-- the formal types of the generic package 7

generic 8

type Node **is private**;

type Link **is access** Node;

package P **is**

 ...

end P;

-- can be matched by the actual types 9

type Car; 10

type Car_Name **is access** Car;

type Car **is** 11

record

 Pred, Succ : Car_Name;

 Number : License_Number;

 Owner : Person;

end record;

-- in the following generic instantiation 12

13 **package R is new P(Node => Car, Link => Car_Name);**

Incompatibilities With Ada 83

13.a The check for matching of designated subtypes is changed from a run-time check to a compile-time check. The Ada 83 rule that “If the designated type is other than a scalar type, then the designated subtypes shall be either both constrained or both unconstrained” is removed, since it is subsumed by static matching.

Extensions to Ada 83

13.b Formal access-to-subprogram subtypes and formal general access types are new concepts.

Wording Changes from Ada 95

13.c/2 {AI95-00231-01} Added a matching rule for subtypes that exclude null.

13.d/2 {AI95-00442-01} We change to “determines a category” as that is the new terminology (it avoids confusion, since not all interesting properties form a class).

Incompatibilities With Ada 2005

13.e/3 {AI05-0288-1} **Correction:** Matching of formal access-to-subprogram types now uses subtype conformance rather than mode conformance, which is needed to plug a hole. This could cause some instantiations legal in Ada 95 and Ada 2005 to be rejected in Ada 2012. We believe that formal access-to-subprogram types occur rarely, and actuals that are not subtype conformant are rarer still, so this should not happen often. (In addition, one popular compiler has a bug that causes such instances to be rejected, so no code compiled with that compiler could have an incompatibility.)

12.5.5 Formal Interface Types

1/2 {AI95-00251-01} {AI95-00442-01} [The category determined for a formal interface type is the category of all interface types.]

1.a/2 **Proof:** {AI95-00442-01} This rule follows from the rule in 12.5 that says that the category is determined by the one given in the name of the syntax production. The effect of the rule is repeated here to give a capsule summary of what this subclause is about.

1.b/2 **Ramification:** Here we're taking advantage of our switch in terminology from “determined class” to “determined category”; by saying “category” rather than “class”, we require that any actual type be an interface type, not just some type derived from an interface type.

Syntax

2/2 {AI95-00251-01} **formal_interface_type_definition ::= interface_type_definition**

Legality Rules

3/2 {AI95-00251} {AI95-00401} The actual type shall be a descendant of every progenitor of the formal type.

4/2 {AI95-00345} The actual type shall be a limited, task, protected, or synchronized interface if and only if the formal type is also, respectively, a limited, task, protected, or synchronized interface.

4.a/2 **Discussion:** We require the kind of interface type to match exactly because without that it is almost impossible to properly implement the interface.

Examples

```
5/2        {AI95-00433-01} type Root_Work_Item is tagged private;
6/2        {AI95-00433-01} generic
type Managed_Task is task interface;
type Work_Item(<>) is new Root_Work_Item with private;
package Server_Manager is
task type Server is new Managed_Task with
entry Start(Data : in out Work_Item);
end Server;
end Server_Manager;
```

{AI95-00433-01} This generic allows an application to establish a standard interface that all tasks need to implement so they can be managed appropriately by an application-specific scheduler. 7/2

Extensions to Ada 95

{AI95-00251-01} {AI95-00345-01} {AI95-00401-01} {AI95-00442-01} The formal interface type is new. 7.a/2

12.6 Formal Subprograms

[Formal subprograms can be used to pass callable entities to a generic unit.] 1

Language Design Principles

Generic formal subprograms are like renames of the `explicit_generic_actual_parameter`. 1.a

Syntax

{AI95-00260-02} `formal_subprogram_declaration ::= formal_concrete_subprogram_declaration | formal_abstract_subprogram_declaration` 2/2

{AI95-00260-02} {AI05-0183-1} `formal_concrete_subprogram_declaration ::= with subprogram_specification [is subprogram_default] [aspect_specification];` 2.1/3

{AI95-00260-02} {AI05-0183-1} `formal_abstract_subprogram_declaration ::= with subprogram_specification is abstract [subprogram_default] [aspect_specification];` 2.2/3

{AI95-00348-01} `subprogram_default ::= default_name | <> | null` 3/2

`default_name ::= name` 4

{AI95-00260-02} {AI95-00348-01} A `subprogram_default` of `null` shall not be specified for a formal function or for a `formal_abstract_subprogram_declaration`. 4.1/2

Reason: There are no null functions because the return value has to be constructed somehow. We don't allow null for abstract formal procedures, as the operation is dispatching. It doesn't seem appropriate (or useful) to say that the implementation of something is null in the formal type and all possible descendants of that type. This also would define a dispatching operation that doesn't correspond to a slot in the tag of the controlling type, which would be a new concept. Finally, additional rules would be needed to define the meaning of a dispatching null procedure (for instance, the convention of such a subprogram should be intrinsic, but that's not what the language says). It doesn't seem worth the effort. 4.a/2

Name Resolution Rules

The expected profile for the `default_name`, if any, is that of the formal subprogram. 5

Ramification: {AI05-0299-1} This rule, unlike others in this subclause, is observed at compile time of the `generic_declaration`. 5.a/3

The evaluation of the `default_name` takes place during the elaboration of each instantiation that uses the default, as defined in 12.3, "Generic Instantiation". 5.b

For a generic formal subprogram, the expected profile for the actual is that of the formal subprogram. 6

Legality Rules

{AI05-0239-1} The profiles of the formal and any named default shall be mode conformant. 7/3

Ramification: {AI05-0299-1} This rule, unlike others in this subclause, is checked at compile time of the `generic_declaration`. 7.a/3

{AI05-0239-1} The profiles of the formal and actual shall be mode conformant. 8/3

{AI95-00423-01} For a parameter or result subtype of a `formal_subprogram_declaration` that has an `explicit_null_exclusion`: 8.1/2

- 8.2/2
- if the actual matching the `formal_subprogram_declaration` denotes a generic formal object of another generic unit G , and the instantiation containing the actual that occurs within the body of a generic unit G or within the body of a generic unit declared within the declarative region of the generic unit G , then the corresponding parameter or result type of the formal subprogram of G shall have a `null_exclusion`;
- 8.3/2
- otherwise, the subtype of the corresponding parameter or result type of the actual matching the `formal_subprogram_declaration` shall exclude null. In addition to the places where Legality Rules normally apply (see 12.3), this rule applies also in the private part of an instance of a generic unit.
- 8.a/2
- Reason:** This rule prevents “lying”. `Null` must never be the value of a parameter or result with an explicit `null_exclusion`. The first bullet is an assume-the-worst rule which prevents trouble in generic bodies (including bodies of child generics) when the formal subtype excludes null implicitly.
- 8.4/3
- {AI95-00260-02} {AI05-0296-1} If a formal parameter of a `formal_abstract_subprogram_declaration` is of a specific tagged type T or of an anonymous access type designating a specific tagged type T , T is called a *controlling type* of the `formal_abstract_subprogram_declaration`. Similarly, if the result of a `formal_abstract_subprogram_declaration` for a function is of a specific tagged type T or of an anonymous access type designating a specific tagged type T , T is called a controlling type of the `formal_abstract_subprogram_declaration`. A `formal_abstract_subprogram_declaration` shall have exactly one controlling type, and that type shall not be incomplete.
- 8.b/2
- Ramification:** The specific tagged type could be any of a formal tagged private type, a formal derived type, a formal interface type, or a normal tagged type. While the last case doesn't seem to be very useful, there isn't any good reason for disallowing it. This rule ensures that the operation is a dispatching operation of some type, and that we unambiguously know what that type is.
- 8.c/2
- We informally call a subprogram declared by a `formal_abstract_subprogram_declaration` an *abstract formal subprogram*, but we do not use this term in normative wording. (We do use it often in these notes.)
- 8.5/2
- {AI95-00260-02} The actual subprogram for a `formal_abstract_subprogram_declaration` shall be a dispatching operation of the controlling type or of the actual type corresponding to the controlling type.
- 8.d/2
- To be honest:** We mean the controlling type of the `formal_abstract_subprogram_declaration`, of course. Saying that gets unwieldy and redundant (so says at least one reviewer, anyway).
- 8.e/2
- Ramification:** This means that the actual is either a primitive operation of the controlling type, or an abstract formal subprogram. Also note that this prevents the controlling type from being class-wide (with one exception explained below), as only specific types have primitive operations (and a formal subprogram eventually has to have an actual that is a primitive of some type). This could happen in a case like:
- 8.f/2
- ```
generic
 type T(<>) is tagged private;
 with procedure Foo (Obj : in T) is abstract;
package P ...
```
- 8.g/2
- ```
package New_P is new P (Something'Class, Some_Proc);
```
- 8.h/2
- The instantiation here is always illegal, because `Some_Proc` could never be a primitive operation of `Something'Class` (there are no such operations). That's good, because we want calls to `Foo` always to be dispatching calls.
- 8.i/2
- Since it is possible for a formal tagged type to be instantiated with a class-wide type, it is possible for the (real) controlling type to be class-wide in one unusual case:
- 8.j/2
- ```
generic
 type NT(<>) is new T with private;
 -- Presume that T has the following primitive operation:
 -- with procedure Bar (Obj : in T);
package Gr ...
```
- 8.k/2
- ```
package body Gr is
  package New_P2 is new P (NT, Foo => Bar);
end Gr;
```
- 8.l/2
- ```
package New_Gr is new Gr (Something'Class);
```
- 8.m/2
- The instantiation of `New_P2` is legal, since `Bar` is a dispatching operation of the actual type of the controlling type of the abstract formal subprogram `Foo`. This is not a problem, since the rules given in 12.5.1 explain how this routine dispatches even though its parameter is class-wide.

- Note that this legality rule never needs to be rechecked in an instance (that contains a nested instantiation). The rule only talks about the actual type of the instantiation; it does not require looking further; if the actual type is in fact a formal type, we do not intend looking at the actual for that formal. 8.n/2
- Static Semantics*
- A `formal_subprogram_declaration` declares a generic formal subprogram. The types of the formal parameters and result, if any, of the formal subprogram are those determined by the `subtype_marks` given in the `formal_subprogram_declaration`; however, independent of the particular subtypes that are denoted by the `subtype_marks`, the nominal subtypes of the formal parameters and result, if any, are defined to be nonstatic, and unconstrained if of an array type [(no applicable index constraint is provided in a call on a formal subprogram)]. In an instance, a `formal_subprogram_declaration` declares a view of the actual. The profile of this view takes its subtypes and calling convention from the original profile of the actual entity, while taking the formal parameter names and `default_expressions` from the profile given in the `formal_subprogram_declaration`. The view is a function or procedure, never an entry. 9
- Discussion:** This rule is intended to be the same as the one for renamings-as-declarations, where the `formal_subprogram_declaration` is analogous to a renaming-as-declaration, and the actual is analogous to the renamed view. 9.a
- {AI05-0071-1} {AI05-0131-1} If a `subtype_mark` in the profile of the `formal_subprogram_declaration` denotes a formal private or formal derived type and the actual type for this formal type is a class-wide type *T*Class, then for the purposes of resolving the corresponding actual subprogram at the point of the instantiation, certain implicit declarations may be available as possible resolutions as follows: 9.1/3
- For each primitive subprogram of *T* that is directly visible at the point of the instantiation, and that has at least one controlling formal parameter, a corresponding implicitly declared subprogram with the same defining name, and having the same profile as the primitive subprogram except that *T* is systematically replaced by *T*Class in the types of its profile, is potentially use-visible. The body of such a subprogram is as defined in 12.5.1 for primitive subprograms of a formal type when the actual type is class-wide. 9.2/3
- Reason:** {AI05-0071-1} {AI05-0131-1} This gives the same capabilities to formal subprograms as those that primitive operations of the formal type have when the actual type is class-wide. We do not want to discourage the use of explicit declarations for (formal) subprograms! 9.b/3
- Implementation Note:** {AI05-0071-1} {AI05-0131-1} Although the above wording seems to require constructing implicit versions of all of the primitive subprograms of type *T*, it should be clear that a compiler only needs to consider those that could possibly resolve to the corresponding actual subprogram. For instance, if the formal subprogram is a procedure with two parameters, and the actual subprogram name is `Bar` (either given explicitly or by default), the compiler need not consider primitives that are functions, that have the wrong number of parameters, that have defining names other than `Bar`, and so on; thus it does not need to construct implicit declarations for those primitives. 9.c/3
- Ramification:** {AI05-0071-1} {AI05-0131-1} Functions that only have a controlling result and do not have a controlling parameter of *T* are not covered by this rule, as any call would be required to raise `Program_Error` by 12.5.1. It is better to detect the error earlier than at run time. 9.d/3
- If a generic unit has a `subprogram_default` specified by a box, and the corresponding actual parameter is omitted, then it is equivalent to an explicit actual parameter that is a usage name identical to the defining name of the formal. 10
- {AI95-00348-01} If a generic unit has a `subprogram_default` specified by the reserved word `null`, and the corresponding actual parameter is omitted, then it is equivalent to an explicit actual parameter that is a null procedure having the profile given in the `formal_subprogram_declaration`. 10.1/2
- {AI95-00260-02} The subprogram declared by a `formal_abstract_subprogram_declaration` with a controlling type *T* is a dispatching operation of type *T*. 10.2/2
- Reason:** This is necessary to trigger all of the dispatching operation rules. It otherwise would not be considered a dispatching operation, as formal subprograms are never primitive operations. 10.a/2

## NOTES

- 11 13 The matching rules for formal subprograms state requirements that are similar to those applying to `subprogram_renaming_declarations` (see 8.5.4). In particular, the name of a parameter of the formal subprogram need not be the same as that of the corresponding parameter of the actual subprogram; similarly, for these parameters, `default_expressions` need not correspond.
- 12 14 The constraints that apply to a parameter of a formal subprogram are those of the corresponding formal parameter of the matching actual subprogram (not those implied by the corresponding `subtype_mark` in the `_specification` of the formal subprogram). A similar remark applies to the result of a function. Therefore, to avoid confusion, it is recommended that the name of a first subtype be used in any declaration of a formal subprogram.
- 13 15 The subtype specified for a formal parameter of a generic formal subprogram can be any visible subtype, including a generic formal subtype of the same `generic_formal_part`.
- 14 16 A formal subprogram is matched by an attribute of a type if the attribute is a function with a matching specification. An enumeration literal of a given type matches a parameterless formal function whose result type is the given type.
- 15 17 A `default_name` denotes an entity that is visible or directly visible at the place of the `generic_declaration`; a box used as a default is equivalent to a name that denotes an entity that is directly visible at the place of the `_instantiation`.
- 15.a **Proof:** Visibility and name resolution are applied to the equivalent explicit actual parameter.
- 16/2 18 {AI95-00260-02} The actual subprogram cannot be abstract unless the formal subprogram is a `formal_abstract_subprogram_declaration` (see 3.9.3).
- 16.1/2 19 {AI95-00260-02} The subprogram declared by a `formal_abstract_subprogram_declaration` is an abstract subprogram. All calls on a subprogram declared by a `formal_abstract_subprogram_declaration` must be dispatching calls. See 3.9.3.
- 16.2/2 20 {AI95-00348-01} A null procedure as a subprogram default has convention `Intrinsic` (see 6.3.1).
- 16.a.1/2 **Proof:** This is an implicitly declared subprogram, so it has convention `Intrinsic` as defined in 6.3.1.

*Examples*

- 17 *Examples of generic formal subprograms:*
- 18/2 `{AI95-00433-01} with function "+" (X, Y : Item) return Item is <>;`  
`with function Image (X : Enum) return String is Enum'Image;`  
`with procedure Update is Default_Update;`  
`with procedure Pre_Action (X : in Item) is null; -- defaults to no action`  
`with procedure Write (S : not null access Root_Stream_Type'Class;`  
`Desc : Descriptor)`  
`is abstract Descriptor'Write; -- see 13.13.2`  
`-- Dispatching operation on Descriptor with default`
- 19 `-- given the generic procedure declaration`
- 20 `generic`  
`with procedure Action (X : in Item);`  
`procedure Iterate (Seq : in Item_Sequence);`
- 21 `-- and the procedure`
- 22 `procedure Put_Item (X : in Item);`
- 23 `-- the following instantiation is possible`
- 24 `procedure Put_List is new Iterate (Action => Put_Item);`

*Extensions to Ada 95*

- 24.a/2 {AI95-00260-02} The `formal_abstract_subprogram_declaration` is new. It allows the passing of dispatching operations to generic units.
- 24.b/2 {AI95-00348-01} The formal subprogram default of `null` is new. It allows the default of a generic procedure to do nothing, such as for passing a debugging routine.

*Wording Changes from Ada 95*

- 24.c/2 {AI95-00423-01} Added matching rules for `null_exclusions`.

*Incompatibilities With Ada 2005*

- 24.d/3 {AI05-0296-1} It is now illegal to declare a formal abstract subprogram whose controlling type is incomplete. It was never intended to allow that, and such a type would have to come from outside of the generic unit in Ada 2005, so it is

unlikely to be useful. Moreover, a dispatching call on the subprogram is likely to fail in many implementations. So it is very unlikely that any code will need to be changed because of this new rule.

*Extensions to Ada 2005*

{AI05-0071-1} {AI05-0131-1} **Correction:** Added construction of implicit subprograms for primitives of class-wide actual types, to make it possible to import subprograms via formal subprograms as well as by implicit primitive operations of a formal type. (This is a **Correction** as it is very important for the usability of indefinite containers when instantiated with class-wide types; thus we want Ada 2005 implementations to support it.) 24.e/3

{AI05-0183-1} An optional `aspect_specification` can be used in a `formal_concrete_subprogram_declaration` and a `formal_abstract_subprogram_declaration`. This is described in 13.1.1. 24.f/3

## 12.7 Formal Packages

[ Formal packages can be used to pass packages to a generic unit. The `formal_package_declaration` declares that the formal package is an instance of a given generic package. Upon instantiation, the actual package has to be an instance of that generic package.] 1

*Syntax*

{AI05-0183-1} `formal_package_declaration ::=` 2/3  
**with** `package` `defining_identifier` **is new** `generic_package_name` `formal_package_actual_part`  
`[aspect_specification];`

{AI95-00317-01} `formal_package_actual_part ::=` 3/2  
`([others =>] <>)`  
`| [generic_actual_part]`  
`| (formal_package_association {, formal_package_association} [, others => <>])`

{AI95-00317-01} `formal_package_association ::=` 3.1/2  
`generic_association`  
`| generic_formal_parameter_selector_name => <>`

{AI95-00317-01} Any positional `formal_package_associations` shall precede any named `formal_package_associations`. 3.2/2

*Legality Rules*

The `generic_package_name` shall denote a generic package (the *template* for the formal package); the formal package is an instance of the template. 4

{AI05-0025-1} The `generic_formal_parameter_selector_name` of a `formal_package_association` shall denote a `generic_formal_parameter_declaration` of the template. If two or more formal subprograms of the template have the same defining name, then named associations are not allowed for the corresponding actuals. 4.1/3

{AI95-00398-01} A `formal_package_actual_part` shall contain at most one `formal_package_association` for each formal parameter. If the `formal_package_actual_part` does not include “`others => <>`”, each formal parameter without an association shall have a `default_expression` or `subprogram_default`. 4.2/3

{AI05-0200-1} The rules for matching between `formal_package_associations` and the generic formals of the template are as follows: 4.3/3

- If all of the `formal_package_associations` are given by generic associations, the `explicit_generic_actual_parameters` of the `formal_package_associations` shall be legal for an instantiation of the template. 4.4/3

- 4.5/3 • If a `formal_package_association` for a formal type  $T$  of the template is given by  $\diamond$ , then the `formal_package_association` for any other `generic_formal_parameter_declaration` of the template that mentions  $T$  directly or indirectly must be given by  $\diamond$  as well.
- 4.a/3 **Discussion:** *{AI05-0200-1}* The above rule is simple to state, though it does not reflect the fact that the formal package functions like an instantiation of a special kind, where each box association for a `generic_formal_parameter_declaration`  $F$  is replaced with a new entity  $F'$  that has the same characteristics as  $F$ : if  $F$  is a formal discrete type then  $F'$  is a discrete type, if  $F$  is a formal subprogram then  $F'$  is a subprogram with a similar signature, etc. In practice this is achieved by making the association into a copy of the declaration of the generic formal.
- 5/2 *{AI95-00317-01}* The actual shall be an instance of the template. If the `formal_package_actual_part` is ( $\diamond$ ) or (**others**  $\Rightarrow$   $\diamond$ ), [then the actual may be any instance of the template]; otherwise, certain of the actual parameters of the actual instance shall match the corresponding actual parameters of the formal package, determined as follows:
- 5.1/2 • *{AI95-00317-01}* If the `formal_package_actual_part` includes `generic_associations` as well as associations with  $\diamond$ , then only the actual parameters specified explicitly with `generic_associations` are required to match;
- 5.2/2 • *{AI95-00317-01}* Otherwise, all actual parameters shall match[, whether any actual parameter is given explicitly or by default].
- 5.3/2 *{AI95-00317-01}* The rules for matching of actual parameters between the actual instance and the formal package are as follows:
- 6/2 • *{AI95-00317-01}* For a formal object of mode **in**, the actuals match if they are static expressions with the same value, or if they statically denote the same constant, or if they are both the literal **null**.
- 6.a **Reason:** We can't simply require full conformance between the two actual parameter expressions, because the two expressions are being evaluated at different times.
- 7 • For a formal subtype, the actuals match if they denote statically matching subtypes.
- 8 • For other kinds of formals, the actuals match if they statically denote the same entity.
- 8.1/1 *{8652/0039}* *{AI95-00213-01}* For the purposes of matching, any actual parameter that is the name of a formal object of mode **in** is replaced by the formal object's actual expression (recursively).

#### *Static Semantics*

- 9 A `formal_package_declaration` declares a generic formal package.
- 10/2 *{AI95-00317-01}* The visible part of a formal package includes the first list of `basic_declarative_items` of the `package_specification`. In addition, for each actual parameter that is not required to match, a copy of the declaration of the corresponding formal parameter of the template is included in the visible part of the formal package. If the copied declaration is for a formal type, copies of the implicit declarations of the primitive subprograms of the formal type are also included in the visible part of the formal package.
- 10.a/2 **Ramification:** *{AI95-00317-01}* If the `formal_package_actual_part` is ( $\diamond$ ), then the declarations that occur immediately within the `generic_formal_part` of the template for the formal package are visible outside the formal package, and can be denoted by expanded names outside the formal package. If only some of the actual parameters are given by  $\diamond$ , then the declaration corresponding to those parameters (but not the others) are made visible.
- 10.b/3 **Reason:** *{AI05-0005-1}* We always want either the actuals or the formals of an instance to be nameable from outside, but never both. If both were nameable, one would get some funny anomalies since they denote the same entity, but, in the case of types at least, they might have different and inconsistent sets of primitive operators due to predefined operator “reemergence.” Formal derived types exacerbate the difference. We want the implicit declarations of the `generic_formal_part` as well as the explicit declarations, so we get operations on the formal types.
- 10.c **Ramification:** A generic formal package is a package, and is an instance. Hence, it is possible to pass a generic formal package as an actual to another generic formal package.

{AI95-00317-01} For the purposes of matching, if the actual instance *A* is itself a formal package, then the actual parameters of *A* are those specified explicitly or implicitly in the `formal_package_actual_part` for *A*, plus, for those not specified, the copies of the formal parameters of the template included in the visible part of *A*. 11/2

*Examples*

{AI95-00433-01} *Example of a generic package with formal package parameters:* 12/2

```
with Ada.Containers.Ordered_Maps; -- see A.18.6 13/2
generic
 with package Mapping_1 is new Ada.Containers.Ordered_Maps (<>);
 with package Mapping_2 is new Ada.Containers.Ordered_Maps
 (Key_Type => Mapping_1.Element_Type,
 others => <>);

package Ordered_Join is
 -- Provide a "join" between two mappings

 subtype Key_Type is Mapping_1.Key_Type; 14/2
 subtype Element_Type is Mapping_2.Element_Type;
 function Lookup(Key : Key_Type) return Element_Type; 15/2
 ... 16/2
end Ordered_Join;
```

{AI95-00433-01} *Example of an instantiation of a package with formal packages:* 17/2

```
with Ada.Containers.Ordered_Maps; 18/2
package Symbol_Package is
 type String_Id is ... 19/2
 type Symbol_Info is ... 20/2
 package String_Table is new Ada.Containers.Ordered_Maps
 (Key_Type => String,
 Element_Type => String_Id); 21/2
 package Symbol_Table is new Ada.Containers.Ordered_Maps
 (Key_Type => String_Id,
 Element_Type => Symbol_Info); 22/2
 package String_Info is new Ordered_Join(Mapping_1 => String_Table,
 Mapping_2 => Symbol_Table); 23/2
 Apple_Info : constant Symbol_Info := String_Info.Lookup("Apple"); 24/2
end Symbol_Package; 25/2
```

*Extensions to Ada 83*

Formal packages are new to Ada 95. 25.a

*Extensions to Ada 95*

{AI95-00317-01} {AI95-00398-01} It's now allowed to mix actuals of a formal package that are specified with those that are not specified. 25.b/2

*Wording Changes from Ada 95*

{8652/0039} {AI95-00213-01} **Corrigendum:** Corrected the description of formal package matching to say that formal parameters are always replaced by their actual parameters (recursively). This matches the actual practice of compilers, as the ACATS has always required this behavior. 25.c/2

{AI95-00317-01} The description of which operations are visible in a formal package has been clarified. We also specify how matching is done when the actual is a formal package. 25.d/2

*Incompatibilities With Ada 2005*

{AI05-0025-1} {AI05-0200-1} **Correction:** Added missing rules for parameters of generic formal package that parallel those in 12.3, as well as some specific to `<>` parameters. These are technically incompatibilities because generic formal package parameters that Ada 95 and Ada 2005 would have considered legal now have to be rejected. But this should 25.e/3

not be an issue in practice as such formal parameters could not have matched any actual generics. And it is quite likely that implementations already enforce some of these rules.

*Extensions to Ada 2005*

25.f/3 {AI05-0183-1} An optional `aspect_specification` can be used in a `formal_package_declaration`. This is described in 13.1.1.

## 12.8 Example of a Generic Package

1 The following example provides a possible formulation of stacks by means of a generic package. The size of each stack and the type of the stack elements are provided as generic formal parameters.

*Examples*

2/1 *This paragraph was deleted.*

```

3 generic
 Size : Positive;
 type Item is private;
 package Stack is
 procedure Push(E : in Item);
 procedure Pop (E : out Item);
 Overflow, Underflow : exception;
 end Stack;

4 package body Stack is

5 type Table is array (Positive range <>) of Item;
 Space : Table(1 .. Size);
 Index : Natural := 0;

6 procedure Push(E : in Item) is
 begin
 if Index >= Size then
 raise Overflow;
 end if;
 Index := Index + 1;
 Space(Index) := E;
 end Push;

7 procedure Pop(E : out Item) is
 begin
 if Index = 0 then
 raise Underflow;
 end if;
 E := Space(Index);
 Index := Index - 1;
 end Pop;

8 end Stack;
```

9 Instances of this generic package can be obtained as follows:

```

10 package Stack_Int is new Stack(Size => 200, Item => Integer);
 package Stack_Bool is new Stack(100, Boolean);
```

11 Thereafter, the procedures of the instantiated packages can be called as follows:

```

12 Stack_Int.Push(N);
 Stack_Bool.Push(True);
```

Alternatively, a generic formulation of the type Stack can be given as follows (package body omitted):

```

generic
 type Item is private;
package On_Stacks is
 type Stack(Size : Positive) is limited private;
 procedure Push(S : in out Stack; E : in Item);
 procedure Pop (S : in out Stack; E : out Item);
 Overflow, Underflow : exception;
private
 type Table is array (Positive range <>) of Item;
 type Stack(Size : Positive) is
 record
 Space : Table(1 .. Size);
 Index : Natural := 0;
 end record;
end On_Stacks;

```

14

In order to use such a package, an instance has to be created and thereafter stacks of the corresponding type can be declared:

```

declare
 package Stack_Real is new On_Stacks(Real); use Stack_Real;
 S : Stack(100);
begin
 ...
 Push(S, 2.54);
 ...
end;

```

## 13 Representation Issues

{8652/0009} {AI95-00137-01} {AI05-0299-1} [This clause describes features for querying and controlling certain aspects of entities and for interfacing to hardware.] 1/3

### *Wording Changes from Ada 83*

{AI05-0299-1} The subclasses of this clause have been reorganized. This was necessary to preserve a logical order, given the new Ada 95 semantics given in this section. 1.a/3

### 13.1 Operational and Representation Aspects
